I have found by subjecting some very resistant forms to repeated small doses of it—doses that are not large enough appreciably to affect plant life—that reproduction can be prevented. This observation is at least suggestive in considering the effect of the use of tobacco on the race of man. My experiments confirm the general opinion that formaldehyde is the most effective of all germicides. In the form of vapor I found that I could destroy all forms of life with it. Its action seems to be that of a powerful oxidizer and hardener of tissues. It destroys plant tissues as well as animal protoplasm. Many agents seem to be effective, through their mere hardening influence on albuminous matter. Some are distinctly corrosive, actually destroying and disintegrating tissue. I found that the most effective method of applying destructive agents was that of dipping into fluids which were more or less tinctured with the destructive agents—the destructive power being more or less potent according to the strength of the contained effective agent. But this method is, of course, of limited usefulness. The process of diffusing vapors and gases is by far the most generally effective, convenient, and inexpensive method, the diffusion being effected by the application of heat. I found that the effectiveness of vapors and gases thus generated was largely controlled by the distance from the source of generation of the germ or insect treated. These gases and vapors were also effective in proportion to the quickness of generation and their consequent concentration. I used all sorts of apparatuses in generating vapors and gases. Vapors are more effective than dry gases, and they are more effective if applied to dry areas. Moist atmosphere surrounding an insect or germ seems to tend to protect it. I found that many escaped by hiding in the moisture-holding peat and moss above referred to. I used all sorts of apparatuses to generate vapors, commencing with large, costly, and complicated forms, and gradually evolving downward into the simple, inexpensive, and uncomplicated form of a number of small generating devices. I found that the greater the number of points of generation of the destructive vapors I used, the greater was the success, and this brings me to the point of my communication, viz., that in order to secure the best effect in methods of disinfection, a large number of points of generation and a quick liberation or formation of the disinfecting vapor should be used. In my greenhouse work I use a number of small generators, such as is outlined in the accompanying cut, distributed around the area of the house operated on. A little wood alcohol is placed in the generator lamps and lighted. The disinfecting material is put in the superimposed evaporating-pan, and the apparatuses are left to do their very perfect work. It is obvious that the same method can be applied to house disinfection. Small generators can be placed in the several parts of a room, in corners, in closets, and under beds, and will produce very much more germicidal effect, and at much less expense and labor, than in using one large apparatus, the vapor from which may be, perhaps, applied through a keyhole. By using this diffuse method of generation, of course, any degree of concentration and strength of disinfecting vapors can be obtained by merely multiplying the number of generators.

Lymphatic and Portal Affections following Appendicitis.—J. C. Munro believes 1. That the retroperitoneal lymphatics are probably always infected to

some extent in inflammation of the appendix, the degree of the infection not necessarily depending on the extent of the appendical inflammation; a mild, chronic appendicitis at times giving rise to a severe lymphangitis. 2. That the lymphatic disturbance may date its origin from an appendicitis occurring many months beforehand. 3. That a lymphatic infection severe enough to warrant local treatment is rare when compared with all the cases of appendicitis, but that such an affection is probably more common than a portal infection. 4. That mild infections of both the lymphatics and of the portal system may yield to medical treatment. 5. That persistent fever, without other evident cause, should suggest one or both of these infections. 6. That spasm, tenderness, and later fulness in the right loin should indicate a retroperitoneal infection from some source or other, possibly due to an appendicitis, though due in many cases to renal, hepatic, pleural, or other lesions. 7. That chills and hepatic tenderness, associated at times with jaundice, may be of appendical origin, and that this origin, especially in obscure cases, should be sought for most carefully in physical examination, in the personal history, and, if necessary, in abdominal exploration. 8. That drainage in the loin gives prompt and satisfactory relief when pus or even a diffuse cellulitis has formed. 9. That prompt and thorough drainage of the liver, together with removal of the inflamed appendix, offers the best means for recovery from septic infections of the liver. 10. That aspiration of the liver is an imperfect, unsatisfactory, and unsurgical procedure. Abdominal section with definite, free exploration of the liver and free opening of all abscesses within reach is far more satisfactory, not difficult, and less dangerous than aspiration.—*St. Louis Medical and Surgical Journal*, February, 1901.

Rhus Glabra in Enuresis.—J. J. Cassidy states that the internal use of rhus glabra will prevent incontinence of urine. Its action resembles that of tannic acid. The writer reports the cases of three lads treated from February 23 to June 24, 1900, their ages ranging from twelve to fourteen years. The prescriptions used were as follows:

℞ Ferri citratis..... gr. clx.
Syrupi calcii lactophosphatis,
Syrupi cascaræ aromatici.....āā ʒ ij.
M. S. A teaspoonful after dinner (noon).

℞ Extracti rhois glabræ fluidi..... ♏ cccxx.
Syrupi.....q.s. ad ʒ ij.
M. S. A teaspoonful at bedtime.

The cure probably resulted from the continued action of the vegetable astringent on the vesical mucosa, and particularly the fibres of the sphincter vesicæ. These medicines proved successful in three relapsing cases of enuresis, and two of the patients are known to have remained cured. The third lad did not return for examination.—*The Canadian Journal of Medicine and Surgery*, February, 1901.

Case of Wandering Hydatid.—J. Small reports the case of a man forty-five years of age, a wool classer. The man had always been well and strong; he did not smoke or drink. He presented himself with a large swelling on the right dorsal surface of the chest—showing through the clothes. About three years previous, the patient heard a crack and at once a swelling about as large as a saucer appeared. There was no pain, cough, or inconvenience. On rubbing, it sometimes became flatter and smaller. The final diagnosis before operation was a hydatid. This proved to be correct. The cyst contained from three to four pints of purulent fluid. The wound was dressed daily. Five days after the operation, the discharge proved to be pure bile. A month after operation, the wound was perfectly healed. The writer calls attention to the remarkable fact that a cyst could emigrate from the liver, perforate the diaphragm, pleura, etc., and finally erode and burst through a rib—for there was discovered a round hole in one of the ribs—all without causing pain, discomfort, or cough.—*Intercolonial Medical Journal of Australasia*, January 20, 1901.

Congenital Hypertrophic Stenosis of the Pylorus, with an Account of a Case Successfully Treated by Operation.—James H. Nicoll reports the case of a child of five weeks, who vomited the entire contents of his stomach in fifteen to twenty minutes after each meal. The vomiting was a prompt and complete ejection of the milk previously taken, in large part clotted but not otherwise changed. There was no hiccough, nausea, or pain. The writer carried out an operation which was practically a Loreta's. The infant made a perfect recovery, the effect of the operation being complete relief of the previous obstruction. At the present date, twelve and one-half months after operation, except that he is slightly rickety, the child remains in perfect health. Various theories have been advanced as to the causation of this affection. 1. That the condition is the result of a congenital developmental aberration. 2. That it is the result of a congenital hypertrophy of the pyloric muscles, and secondary to antagonistic and inco-ordinated action of the stomach on the one hand and the pylorus on the other; this inco-ordination depending on functional disorders of the gastric nervous system, and resulting in "congenital gastric spasm." 3. That it results from spasmodic contraction arising from gastric irritation after birth, and therefore not congenital. 4. That the condition is the result of chronic inflammatory processes.—*Pediatrics*, February 1, 1901.

A Method of Repairing the Divided Ureter by Direct Suture.—A. Gubaroff in removing a large fibrosarcoma was obliged to resect a portion of the ureter. In repairing the injury a very simple method of suturing was resorted to, but owing to the patient's death a month later, from causes independent of the operation, an examination of the result was made possible. The lower stump was nicked longitudinally to admit the entrance of the upper one, and the two were held in position by a single suture. A sound was now introduced and the suturing continued until the longitudinal slit had to be closed, when the sound was withdrawn and the previously inserted sutures were tightened, whereby close union was obtained. By this method all the openings in the ureter are longitudinal, and it has been shown that such heal readily, without the formation of fistulæ. The most important factor in the operation is to secure early and complete peritoneal adhesions: the sutures serve only until this shall have taken place, and hence are to be of quickly absorbable material, such as very fine reindeer sinew On autopsy it was found that perfect union with no narrowing of the lumen had been obtained.—*Centralblatt f. Chirurgie*, February 2, 1901.

Chromic Acid Used as a Cauterant, Followed by Toxic Action.—John W. Shaw reports the case of a young woman apparently in the best of health, but whose labia majora were covered by a mass of vegetations, extending upward toward the pubis and downward toward the anus. These had been variously treated but had constantly recurred. An anæsthetic was administered, and the usual solution of chromic acid applied, of the strength of one hundred grains to the ounce of water, the surrounding parts being carefully protected. Less than a half-ounce of the acid solution was used. The case developed into one of chromic-acid poisoning. The patient remained in an

extreme condition for about thirty-six hours, after which she gradually returned to a normal state, and after two weeks was able to leave her room. As to the literature on the subject, a few of the therapeutists mention that death has been produced by local applications of the acid. The probable explanation of what occurred in this case is that the chromic acid was absorbed and entered into combination with the sodium of the sodium carbonate of the blood to form sodium chromate. The writer propounds the question, Is this well-known remedy to be used in similar cases?—*Virginia Medical Semi-Monthly*, February 8, 1901.

Metabolism in Old Age.—Géza Kövesi investigated the changes occurring in bodily activity in old age by studying the excretions of two individuals, aged seventy-six and seventy-eight years respectively, kept for varing periods of time on diets whose chemical composition was accurately determined beforehand. It was found that the caloric needs of the body were greatly diminished, but that the consumption of albumin in the intestine proceeded normally. An accumulation of albuminous material could be effected even on a low daily allowance of such food, since the demands of the body for albumin grow less with advancing years. The breaking down of albuminous material also is greatly diminished in the senile state. This double saving, whereby the cell requires less albumin, while at the same time the activity of albuminous decomposition is reduced, does much to explain the processes of senile involution and refers the significance of the bodily changes taking place at this time to alterations in actual cellular metabolism.—*Centralblatt f. innere Medicin*, February 2, 1901.

Subconjunctival Angioma.—Scholtz Kornel reports this case. The patient, wife of a shopkeeper, had noticed this tumor since she was ten years old. The widely opened orbit is to two-fifths of its extent occupied by a dense, flattened swelling. Its posterior surface lies in contact with the eyeball. The new growth protrudes from behind the caruncula, and its shape closely corresponds to the form of the semilunar fold, and the whole swelling is, as a matter of fact, covered by the greatly stretched semilunar fold, with which it is firmly connected, so that it is not movable. The swelling is firmly attached to the tissues at its base, and its size is not much reduced by pressure. The eyelids can be well closed. The tumor was evidently an angioma. Common as are angiomas starting from the eyelids and invading the conjunctiva, cases in which they develop in the conjunctiva itself or under it are nevertheless very rare. The interesting points in the present instance are the unusual form and site of the tumor and the thickness and rigidity of the walls, in consequence whereof the size of the tumor cannot be lessened, even on considerable pressure. —*Medical Press and Circular*, February 13, 1901.

The Treatment of Chronic Myocarditis.—Robert H. Babcock states that, when cardiac inadequacy has once declared itself, there are three principles which should guide its management: The reduction in the amount of work required of the heart; the attempt to restore or support heart power; the treatment of complications. Great judgment should be exercised in advice given to the patient as to the curtailment of heart strain. His zeal must not overbalance common sense. In restoring heart power, resort may be had to drugs, rest, exercise, and the so-called Bad Nauheim treatment. Of drugs, digitalis and its congeners are generally and most commonly employed. For those who are only threatened with, but as yet do not manifest cardiac asthenia, golf is an excellent form of exercise. Bicycling is dangerous for most of these patients. The efficacy of the Bad Nauheim treatment is now recognized by most men of wide experience in this class of heart disease. Chronic nephritis does not contraindicate the Bad Nauheim treatment. When glycosuria and nephritis coexist, together with myocardial degeneration, resistance gymnastics and the balneological treatment are not contraindicated. Angina pectoris may be regarded as a complication, though, strictly speaking, it is but a symptom. The long-continued use of iodide of sodium is highly recommended by the French and by Vierordt. Rumpf insists that the dietary be free as far as possible from articles rich in lime salts.—*The Chicago Medical Recorder*, February, 1901.

The Treatment of Anæmias.—Clifford Allbutt says that recent researches show that in ordinary anæmias there is a reduction of blood as a whole—corpuscles and plasma. In chlorosis, on the other hand, the dilatation of the heart and voluminous if not high-pressure pulse seem to signify increased blood bulk. In the latter, high altitudes would seem to be a better adjuvant in treatment than the use of spa waters, which would have the disadvantage of adding to the bulk of blood already excessive. For the anæmias of impoverishment the colder high climates are not to be sought, but rather watering-places near the sea, with warmth of air, baths, and clothing. These patients are suffering from a defect of function of all the glands of the body, and do well on mineral waters of the muriated class and mild mercurials.—*Medical Press and Circular*, February 20, 1901.

Foreign Body in the Brain.—F. R. Ross reports the case of a man with suicidal tendencies who drove the whole length of a shoemaker's awl into his brain, by placing the handle against a brick wall and driving his head against the point. The handle of the awl fell to the floor and the skin closed over the wound, leaving no evidence of the entrance of the awl except a slightly bruised spot at the point of entrance. He immediately became unconscious, remaining so for several hours, when consciousness returned, and he was apparently no worse for the injury. About one week later his temperature began to rise, the right leg was swollen, he became stuporous, and finally delirious. The fever rose to 105° and 106° F., sweating was profuse, and emaciation rapidly supervened. The symptoms gradually abated, and in a few weeks he was able to resume business. He continued in a varying condition of health for about a year and a half. Part of the time he was quite well, and at other times he suffered from acute melancholia. During one of his lucid intervals he mentioned the fact of his attempt at suicide, but his story was not believed, as there was no scar, and he had no head pains. His story finally gained credence, and an exposure of the skull was made at the site he claimed the awl to have been driven into the brain, viz., one inch posterior to the external angular process and one inch above the zygomatic process; the skin was lifted and the end of the awl was soon exposed, and being grasped with a pair of strong forceps it was removed. Attached to it and surrounding it was a fibrous sheath, and to the sheath was attached a small portion of brain tissue. Recovery from the operation was uneventful, and in two weeks the man was up and about. The author does not believe that the foreign body in the brain had anything whatever to do with his insanity, since he was insane before its entrance, and there was an undeniable history of heredity in his family, and heredity unquestionably was the cause of the mental aberration. Neither did the awl's removal aid in his recovery, for recovery took place at first before its removal, and was nearly completed the second time before the awl was removed. The case is reported to illustrate the tolerance of brain tissue.—*Texas Medical Gazette*, February, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 30, 1901.

THE ROENTGEN RAYS IN PRACTICAL MEDICINE.

ALTHOUGH scarcely more than five years have elapsed since the discovery by Roentgen of the light waves now generally known by his name, great advances have been made in the practical application of this somewhat mysterious form of energy. While perhaps unjustified predictions were made and false hopes aroused by reckless propagandists in the primary enthusiasm born of a startling revelation, the new rays have, nevertheless, proved themselves of distinct diagnostic and therapeutic service. On the other hand, it was at one time feared that the prolonged exposure thought necessary for successful observation would interfere with the usefulness of the procedure. Great improvements have, however, been made in the technique, so that admirable results can now be obtained within extraordinarily brief periods. An interesting review of the applications of the *x*-rays in medical practice has recently been published by Kümmell (*Berliner klin. Wochenschrift*, 1901, Nos. 1 and 2). With the aid of the rays, a diagnosis is possible at times, and with a precision that could not be attained in any other way. The rays were employed first and most extensively for the detection of foreign bodies in various parts of the human body. The removal of bodies thus disclosed was at times attended with some difficulty, on account of the failure of the skiagraph to reveal their exact situation; but this was greatly lessened by securing pictures at different planes. This difficulty has been obviated also by the preparation of stereoscopic pictures.

The demonstration of bullets in the extremities, the chest and abdomen, as well as the head; and also of fractures caused by gunshot injuries, has been one of the features of recent military surgery, so that a skiagraphic outfit has become a necessary part of every surgical armamentarium. Dilatation or stenosis of various viscera, as of the œsophagus and the stomach, may be demonstrated by the introduction of concentrated solutions of bismuth or of capsules containing bismuth, or of hollow sounds containing shot, metallic wire, or spirals. Not only the presence of foreign bodies, such as coins, pieces of metal, etc., may be detected by means of the *x*-rays, but also the progress of the Murphy button when it has been employed for anastomotic purposes. Of pathologic concretions, biliary calculi have been but rarely discovered with the aid of skiagraphy, and urinary calculi, especially in the kidney, scarcely more frequently.

By means of the Roentgen rays it is possible, not only to confirm the diagnosis of fracture, but also to detect the presence of complications, such as dislocation, and to observe whether reduction has been properly and completely effected and is correctly maintained. A like statement is applicable to dislocations, simple or complicated. Deformities apparently due to fracture or luxation are occasionally found, with the aid of the *x*-rays, to be merely anatomical anomalies. In the domain of accidental injuries, skiagraphy may be of much value in establishing not alone the presence, but likewise the absence, of actual lesions. It is applicable, further, in the diagnosis of congenital luxation of the hip joint, and in controlling the results of treatment. With its aid the differentiation between congenital luxation and coxa vara can be confirmed. Inflammatory changes in other joints, free bodies, tuberculous or other lesions, osseous and fibrous ankylosis, and the differentiation between traumatic and pathological processes, may be made out. Syphilitic, tuberculous, and osteomyelitic thickening of, and deposits in, long and short medullated bones are readily recognizable in the skiagraphic plate, as is gradually progressive production of new bone, after destruction by osteomyelitis. Sequestra, in process of separation or already detached, can be recognized with great certainty, and the proper time for their removal decided upon. Foci of disease in bone, tuberculous processes in the epiphyses and diaphyses of the long bones, osteomyelitic lesions and bone abscesses are clearly demonstrable, and are thus rendered amenable to treatment. Tumors seated upon bones, as well as central osteosarcomata, yield a distinct picture.

The presence of chemical substances, such as combinations of iodine, in any part of the body, as when injected into a joint or other cavity or fistulous tract, can be readily detected. It has been possible by means of skiagrams to demonstrate fine changes in bone, as for instance atrophy after operations on joints, the application of plaster splints, and flaccid paralysis. The existence and the progress of ossifying myositis can be distinctly observed. Arteriosclerosis also can be recognized at times at an early stage. The course and the distribution of the blood-vessels in the spleen can be shown in detail, after injection of opaque material. Good skiagrams of the internal viscera can be obtained after brief exposure. In this way the distended lungs of emphysema, the thickened pleura following inflammatory processes, the presence of empyema with the compressed lung, of pneumothorax, of cavities in the lungs, and of peribronchial foci, of pulmonary gangrene, of abscess of the lung may be shown. The shadows of the heart, the aorta, of aneurisms, and of mediastinal tumors, have also been useful in diagnosis.

In the technique the preparation of stereoscopic pictures has been a marked advance. This requires exposure in rapid succession of each half of the plate, without change of posture. Great improvement has been made in induction apparatus, so that sparks of

from 40 to 60 cm. and more are easily obtained. The current interrupter is an important adjunct of the apparatus, and one of electrolytic mechanism has proved exceedingly useful. Much importance is to be attached to the character of the tubes, which should be properly exhausted and sufficiently soft. The preparation of good pictures requires much skill and experience. The *x*-rays have also rendered valuable aid therapeutically, being applicable especially in the treatment of diseases of the skin. Among diseases that have been successfully submitted to the action of this agent, are lupus vulgaris, lupus erythematosus, chronic eczema, vascular nævus, hypertrichosis, favus, and sycosis.

It will thus be seen that the *x*-rays have become an important, and in the hands of the careful clinician, a reliable aid in the diagnosis of various conditions. As with other methods of investigation, their employment is hedged in with certain possibilities of error; but these will be avoided if it be borne in mind that the results yielded by it are purely physical, and that, after all, their interpretation must be made by an intelligent mind.

TUBERCLE BACILLI DISSEMINATED BY COWS IN COUGHING, AS A POSSIBLE SOURCE OF CONTAGION.

The general belief at the present time that the means by which tuberculosis is chiefly disseminated, by the inhalation of dried tuberculous sputum which becomes pulverized and is carried about by currents of air, or put into motion in other ways, has been strongly substantiated by numerous experiments. Flügge, however, is not in accord with these views, and is of the opinion that the spread of tuberculosis is due mainly to the inhalation of minute particles of sputum which the act of coughing thus ejects. He further holds that these particles float in the air for a considerable period of time, and may be blown hither and thither by very slight currents. Klebs, in this country, has demonstrated the fact that, during the act of coughing, minute particles of sputum, often containing tubercle bacilli, are thrown out. At his instance, too, Dr. Curry, of Boston, carried out a series of elaborate experiments (*Boston Medical and Surgical Journal*, October, 1898, vol. cxxxix., No. 15) with the object of thoroughly investigating the matter. Dr. Curry concluded from his experiments that, although there is a possible, and even a probable, danger from this source, Flügge has greatly exaggerated this danger. Dr. Mazyck, lecturer and demonstrator of bacteriology, veterinary department, University of Pennsylvania, has been led to undertake experiments to see if it were not possible that cows in the act of coughing would likewise expel small particles of tuberculous material rich in tubercle bacilli. The results of these studies were made the subject of a paper by Dr. Mazyck, which was read before the Pathological Society of Philadelphia on November 8, 1900. The belief is common that cows when coughing swallow all their sputum, and do not project it to any extent. Dr. Mazyck, by ingenious methods devised by himself, has disproved this theory, and has practically demonstrated that, in the act of coughing, cows, as well as men, atomize, so to speak, their sputum, and project it into the air in minute particles, which may float for some time. Inoculation of guinea-pigs with this secretion gave a considerable proportion of positive results. Dr. Mazyck came to the conclusion that the danger of infection by means of this atomized sputum, as far as mankind goes, is confined practically to those in constant contact with the animals, but for other animals in the same stable the infected animals must be considered a source of danger. The moral to be derived from the outcome of Dr. Mazyck's experiments would seem to be that when tuberculosis is diagnosed in a cow, she should be as far as is possible isolated—at any rate, she should not be confined in a shed with healthy animals.

GELATIN INJECTIONS FOR ANEURISM.

Aneurisms of the great vessels of the body are such unsatisfactory things to treat, both medically and surgically, that anything which promises an advance in this connection should have a fair hearing. During the past two or three years a number of attempts have been made to cope with certain aneurisms beyond the reach of radical surgical intervention, by means of the subcutaneous injection of solutions of gelatin, administered with the view of increasing the coagulability of the blood. There have been numbers of cases reported by different observers, most of whom are on the continent of Europe. The technique of the injection has usually been the same among all operators, and consists in the subcutaneous injection of a sterile solution of gelatin, to the amount of about 250 c.c., at intervals of two or more days. The strength of the solution has usually been one or two per cent., and no serious local disturbances have been reported.

Geraldini, an Italian observer, reports (*Gaz. degli Osped.*, February, 1901) four aortic aneurisms, in the treatment of which he made use of this method, with great apparent benefit, though the details are not given with quite as much completeness as is desirable. In one patient who had an aneurism involving the innominate artery, the benefit was apparently very great. Forty-five injections were given in all, and the tumor ceased to pulsate, and diminished in prominence. Another patient with an aortic aneurism received sixty injections, and much benefit was claimed. In this case, albuminuria developed during the course of the treatment, so that the injections were discontinued for a number of days. In the other two cases in this series marked improvement was also noted. A number of other writers have reported more or less similar favorable experiences, and several cases have been reported in which no benefit was seen, but the four cases mentioned above are of enough importance to gain attention for the method, and to make it advisable to pursue the matter under proper circumstances.

The gelatin is said to act, as would naturally be supposed, by increasing the coagulability of the blood, though it seems to us that the limit of safety in this in-

crease must very soon be reached if the cause of the increase is mechanical—that is, solution of the gelatin in the plasma. It does not appear that the plasma could exercise its physiological functions with more than a very small percentage of gelatin in solution in it. We must not, furthermore, be too ready to decide favorably in the case of this method, until we are able to judge in how great a degree other recognized means of treatment have been employed, from which many favorable results have heretofore been reported. Potassium iodide, rest, and restricted diet have often given at least temporary satisfaction in cases of aneurism of the great vessels, and a large share of a good result might really be due to such means, when the disposition would be to credit the novel method with the good done, without making due allowance for the adjuvants.

Several instances of the employment of the method in this country have been reported, in which there has been no perceptible improvement, and apparently the physiological limit of its applicability and safety would seem to be very considerably on this side of the point at which mechanical suspension of gelatin in the blood plasma would be sufficient to exercise its power of increasing coagulability to a sufficient extent.

However, more clinical evidence is what is needed, and as, with proper precautions, there seems to be no danger in the employment of this method, there is no objection to asking for further trials. Evidence is not likely to accumulate very fast, since aneurism is not a very common disease here; but the burden of the proof lies with the new method.

THE HEALTH OF NOME.

From time to time reports have been circulated with regard to the prevalence of sickness, and especially of smallpox, in Nome, Alaska. The ordinary reader of the newspaper from a perusal of some of these accounts might be led to believe that Nome was a veritable death trap, where to go would be to court at least serious danger to health. Dr. Call, health physician in that town, sent in October last, at the request of Lieut. D. H. Jarvis, acting United States treasury agent there, a true account of the state of affairs. He reports that smallpox was introduced into Nome by the steamship *Oregon*, whose captain surreptitiously removed two cases of the disease from the vessel to Nome River, about three miles east of the city. As Dr. Call was aware that the climatic and sanitary conditions of Nome were such that the malady would spread rapidly, immediate steps were taken to prevent this occurrence. A smallpox hospital was established, and other measures for fighting the disease efficiently were put into force. The result was that, at any time, there were no more than thirty-one cases. The first case developed on June 17th, and the last on August 2d. On August 27th, the few remaining cases were discharged from the smallpox hospital, and the following day the camp which had been formed outside the town was destroyed by fire. Dr. Call states that, generally speaking, the course of the disease was mild, similar to that of the epidemic in the spring and summer of 1900, in the northwestern United States. Of the patients who came under Dr. Call's immediate notice, sixteen had never been vaccinated, and of these cases he remarks that five were of moderate severity, one was severe, and ten were mild; showing pretty conclusively that there exists to-day an hereditary immunity in countries recognizing vaccination. Undoubtedly the virulence of the outbreak in Nome has been greatly exaggerated; but the physicians of the town must be commended for their successful energetic efforts to stamp out the disease before it had gained a foothold.

News of the Week.

Ambulance and Car in Collision. — On Sunday, March 24th, while crossing Sixth Avenue at Thirty-eighth Street, an empty New York Hospital ambulance was struck by an electric car and overturned. Both the driver and the surgeon of the ambulance were thrown out and slightly hurt.

American Laryngological Association. — The twenty-third annual congress of the association will be held at New Haven, Conn., Monday, Tuesday, and Wednesday, May 27–29, 1901. The president of the congress is Dr. Henry L. Swain, of New Haven.

Bellevue Physician Dead of Scarlet Fever.—A young Bellevue physician, Dr. Ralph J. Hess, twenty-seven years of age, died in the Scarlet Fever Hospital on North Brother Island on Sunday, March 24th. He is supposed to have contracted the disease while working among the poor on the East Side. The progress of the malady was very rapid, as it was recognized that he was suffering from scarlet fever only on March 19th.

New York Medico-Surgical Society.—At the annual meeting of the New York Medico-Surgical Society, held at the Hotel Manhattan, Saturday evening, March 16th, the following officers were elected: *President*, Robert A. Murray, M.D.; *Vice-President*, A. R. Robinson, M.D.; *Member of the Executive Committee*, W. Duff Bullard, M.D.; *Secretary*, J. Arthur Booth, M.D.

Death of a Dublin Professor.—Another great Dublin scientific man has just passed away, in the person of George Francis Fitzgerald, F.R.S., D.Sc., professor of experimental science in the University of Dublin. Dr. Fitzgerald, who was only forty-nine years of age, had held his professorship for twenty years and was one of the most deservedly popular teachers in the university of the Irish capital.

The Late Professor von Pettenkofer.—A post-mortem examination of the body of the late Professor von Pettenkofer, made by Professor Bollinger, showed the presence of chronic inflammation of the dura mater, which had caused marked thickening and hypertrophy, considerable calcification of the cerebral arteries, chronic arthritis deformans of the right knee joint, and gall stones in the gall bladder. The distinguished

hygienist had suffered from diabetes for many years; the affected knee caused him much pain from time to time, and his sufferings were greatly intensified during the last week or two of his life by a septic condition of the throat and mouth.—*British Medical Journal.*

Smallpox on a Steamer.—The Anchor Line steamer *Britannia*, which arrived March 26th from Marseilles, Genoa, Leghorn, and Naples, was detained at quarantine on Monday, owing to a case of smallpox among the steerage passengers. The patient is convalescent and has been removed to North Brother Island.

Sudden Death of a Lady Physician.—Dr. Mary S. West, 122 East Twenty-eighth Street, died very suddenly on Sunday, March 24th. Dr. Frank King, 141 Lexington Avenue, who had been attending her for some time, thought that the circumstances of the case justified him in reporting it at the coroner's office. Coroner's Physician O'Hanlon examined the body and decided that the deceased died of apoplexy.

Minnesota Bill to Regulate Marriages.—The State senate on Friday, March 22d, reconsidered and finally passed Senator Chilton's bill prohibiting the marriage of insane, epileptic, and idiotic persons, and requiring a medical certificate of all applicants for marriage licenses. Amendments were adopted making the physician's certificate not quite so sweeping, and permitting the marriage of any feeble-minded person over forty-five, the bill originally having extended such permission only to women.

Chicago Eye, Ear, Nose, and Throat College.—This college on February 1st moved into a new building situated at 206 Washington Street, southeast corner of Franklin Street. The reason for this move was that hospital facilities having been added to the school, the building formerly occupied was not sufficiently commodious. The present building, which is a four-story and basement one, has the three upper stories given over to hospital purposes, the remaining two floors being devoted to recitation and out-patient rooms. The addition of a hospital to an institution devoted expressly to the teaching of eye, ear, and nose work is, we believe, a unique feature in this country.

The Plague at the Cape.—The reports from Cape Town with regard to the plague, says *The Medical Press and Circular*, continue to be of a most disquieting nature. The colonial office has at length shown public, official recognition of the epidemic, and on February 27th published returns for the week ending February 23d, as follows: Twenty-nine cases remained under treatment at the end of the previous week; seven deaths have occurred since the commencement of the outbreak; twenty-one still under treatment; one hundred and sixty-seven contacts. Many fresh cases have since been reported, and the city has been placed under strict sanitary supervision. The full control of the city as regards plague has been handed over to a special commission. One of the chief measures is a systematic house-to-house cleansing, and a wholesale cleaning out of the native quarters.

Memorial to Dr. Jacob.—Subscriptions are being collected for the purpose of raising a memorial to the late Dr. Archibald Hamilton Jacob.

Ravages of the Indian Famine.—According to census returns just issued, the population of the central provinces of India has decreased by 1,100,000 as a result of the famine.

A Lady House Surgeon in England.—For the first time in the history of the York dispensary, a lady house surgeon has been appointed. This it was stated had been done "with a full knowledge of all the difficulties and objections that might be raised."

Population of Alaska.—According to a bulletin just issued by the census office, the population of Alaska is 63,592. The first United States census in 1880 showed a total of 33,426 and that of 1890, 32,052. The total land surface of Alaska is 590,884 square miles, and the average number of persons to 100 square miles is 11.

State Inebriate Reformatory for Great Britain.—Mr. Ritchie recently stated in the British House of Commons that he had received numerous representations from county authorities urging the establishment of a state inebriate reformatory. He was anxious to comply with these representations, and he was now in communication with the treasury on the subject.

A New Hospital to be Erected.—A new brick and brownstone hospital building, five stories in height, will be erected in One Hundred and Thirty-sixth Street near Amsterdam Avenue for the Hebrew Benevolent and Orphan Asylum Society at an estimated cost of $70,000. The new hospital will be used for emergency purposes.

Institute of Divine Healing.—The Francis Schlatter Institute was incorporated at Albany on March 11th, for the cure of acute and chronic diseases, by means of medicine, osteopathy, and divine healing. The capital stock is $1,500, and the principal office is in New York City. The directors are Benno A. Hollenberg, M.D., Francis Schlatter, and Luverna Schlatter, of 807 Lexington Avenue.

State Board of Health Suggested for Montana.—Many of the influential papers of the State, says the *Sanitarian* for March, favor the creation of a State board of health for Montana. Among others is the Billings *Gazette* which well says that, properly organized and composed of good, reputable members, such a body can do much good to conserve the general health of the State, if its authority is not too much curtailed. It is in the curtailing of necessary authority that most State boards of health have been partial or entire failures.

Parisian Milk.—At the Pasteur Institute Dr. de Rothschild recently gave a lecture in which he stated the conclusions to which his investigations had led him, regarding the unwholesomeness of the milk supply of Paris. He stated emphatically that, unless the milk was boiled, very little of the article sent into Paris was fit to drink. He affirmed of the 600,000 litres of milk

consumed in Paris each day, that only 25,000 litres might be counted as perfectly safe. Treatment with preservative chemicals, or dilution with water, spoiled the remainder, without counting various other sources of contamination. Parisian milk dealers, in contradiction of these definite statements, protest that Dr. de Rothschild bases his figures on a standard of purity that is too high.

New Treatment for Pneumonia.—The *New York Sun* has received a despatch from Paris stating that Dr. Talamon, one of the physicians at the Buchat Hospital, has announced the successful treatment of pneumonia by injecting anti-diphtheritic serum.

Rabies in Rochester.—A committee of three physicians appointed by the mayor of Rochester to investigate the alleged prevalence of rabies in Rochester, has reported that it is much more common than is generally believed. The committee urges the close muzzling of all dogs, with basket wire muzzles.

$500,000 for Victoria Infirmary, Newcastle, England. — Watson Armstrong, heir to the late Lord Armstrong, the well-known big gunmaker and shipbuilder, will present $500,000 to the Victoria Jubilee Infirmary, which has not been finished because of a lack of funds. He says that, had his great-uncle lived long enough to know of Queen Victoria's death, he would have been the first to assist in building the hospital bearing her name.

Fifty Cases of Smallpox in a Small Town.—It is reported from Seaford, Sussex County, Delaware, a town of 1,700 inhabitants, that there are fifty cases of varioloid within its confines. The disease is stated to be of a mild type, and there has been only one death. The Wilmington Methodist Episcopal Conference should have held its annual meeting at Seaford, but was advised by the State board of health not to do so.

India's Birth Rate Lower.—Complete census returns give the population of India as 294,000,000, an increase in the last decade of 7,000,000. Deducting the population of the Beloochistan, Shan states, Chiun Hills, and Sikkim territory, enumerated for the first time, a net increase is shown of only 1.4 per cent., which is due to improved census methods. Thus the population is for the first time stationary. Owing to two famines, mortality from disease, and a great decline in the birth rate, the native states show excessive declines.

Smallpox not Dying Out.—Three deaths from smallpox and eighteen new cases were reported to the board of health last week. Eight of the new cases are from Brooklyn, and the patients are school children, bearing out the prediction made weeks ago by the health-board physicians that the failure of the old Brooklyn school board to enforce vaccination in the schools would result in many cases among the pupils. Very few pupils in Manhattan have had the disease. The physicians of the board are averaging about 10,000 vaccinations a week. There are thousands of persons in this city who have never been vaccinated. The health authorities predict that this month there will be more cases than in any month since the disease became epidemic in November.

Decision in Chicago as to School Vaccination.—Judge Dunne has decided that school authorities have no legal right to exclude from the schools children who have not been vaccinated, unless an emergency which necessitates guarding from smallpox is shown to exist.

The New York Academy of Medicine.—At a stated meeting of the Academy on April 4th, the order will be as follows: Subject: "The Duty of the Public to the Medical Profession." First paper by D. B. St. John Roosa, M.D., LL.D.; second paper by W. H. Thomson, M.D., LL.D. Discussion by Drs. A. H. Smith, F. R. Sturgis, A. Jacobi, F. P. Kinnicutt, and others.

Plague at Southampton. — A case of bubonic plague was reported last week at Southampton, England. The man suffering from the disease was a Lascar who had recently arrived from Cape Town. The authorities have isolated all the persons who have come into contact with the Lascar during the voyage, and the transport is to be thoroughly disinfected. It is believed that the disinfecting cylinders will also kill rats aboard a vessel.

Diphtheria in Montclair.—Diphtheria is prevalent to a somewhat alarming extent in Montclair, N. J. The milk supply was thought to be responsible for the outbreak. The board of health took prompt action in the matter, and upon investigation discovered that two men employed by the Fairfield Dairy were suffering from the disease. The board of health and the medical milk commission of Essex County issued circulars to the effect that for the present the sale of milk be discontinued by the Fairfield Dairy Company.

The "Bell" Medical Bill.—At a regular meeting of the Medical Society of the County of Westchester, the following resolution was adopted:

Resolved, That it would promote the welfare of the people of the State of New York, that the Senate and Assembly should antagonize the passage of the measure known as the "Seymour bill," regulating and legalizing the practice of osteopathy.

At a regular meeting of the Medical Society of the County of Westchester, the following resolution was adopted:

Resolved, That in the interest of public health and safety we heartily endorse the measure known as the "Bell bill," and we earnestly urge the support of this measure on the part of the senator and assemblymen of this district.

Quarantine Rules between the United States and Cuba Modified.—The announcement has been made from Washington that, in view of improved conditions in Cuba, and the fact that the passengers as well as vessels are inspected before leaving Cuban ports by the United States quarantine officers, and suspected luggage is disinfected, the Treasury Department has so modified existing regulations as to permit, until April 15, 1901, travel from Cuba of non-immunes after their

inspection at the port of departure, and necessary disinfection of effects. This waiver includes the northern ports.

Famine in China.—The latest reports from China are not only by no means encouraging but are extremely ghastly. Famine is said to be causing so much distress in the Province of Shensi, that roots and the bark of trees are eagerly eaten, while cannibalism is common.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending March 23, 1901. Medical Director J. B. Parker detached as president of the medical examining-board, Washington, and ordered to the Naval Home, Philadelphia. Medical Director R. A. Marmion detached from the Naval Home, and ordered to duty at the Washington navy yard, as president of the examining-board. Passed Assistant Surgeon J. M. Moore detached from the Port Royal naval station and ordered to the *Franklin*, April 2d. Passed Assistant Surgeon E. S. Bogert detached from the *Massachusetts* and ordered home to wait orders. Assistant Surgeon H. O. Shiffert detached from the *Franklin* and ordered to the *Solace*, April 1st, and to the Asiatic station. Assistant Surgeon J. C. Thompson ordered to the Port Royal station. Assistant Surgeon E. Thompson detached from the *Nashville* and ordered to the *Solace*. Assistant Surgeon H. H. Hass ordered to the naval hospital, New York. Assistant Surgeon W. B. Grove detached from the naval hospital, New York, and ordered to the naval hospital, Norfolk, Va. Surgeon J. F. Bransford retired in accordance with Act of Congress approved February 5, 1901. Assistant Surgeon S. S. Rodman detached from the naval hospital, Mare Island, and ordered to the *Adams*. Assistant Surgeon R. T. Orvis detached from the *Adams* and ordered to the naval hospital, Mare Island. Medical Director E. S. Bogert, retired, detached from recruiting rendezvous, New York, and ordered home. Surgeon H. L. Law, retired, ordered to recruiting rendezvous, Buffalo, N. Y. Surgeon M. H. Crawford detached from recruiting rendezvous, Buffalo, N. Y., and ordered to marine recruiting rendezvous, New York City. Surgeon P. Leach detached from the *Oregon* and ordered to the *Monocacy*. Passed Assistant Surgeon S. G. Evans detached from the *Kentucky* and ordered to the *Concord*. Passed Assistant Surgeon A. Farenholt detached from the *Concord* and ordered to the *Oregon*. Assistant Surgeon W. E. G. High detached from the *Oregon* and ordered to the *Kentucky*.

Twenty Million Dollars Required to Cleanse Chicago Canal.—Expert engineers now declare that the above sum will be needed to clean the river channel of the Chicago drainage canal. But even this large amount of money will not be sufficient to deal with the Calumet river as well. Its flow of sewage into the lake pollutes the water supply, while the continual increase of population along the banks of this river will tend to render this source of pollution more of a menace to health. It is therefore thought that the commission chosen to report upon plans for improvement of the Chicago river will recommend that the entire proposition of disposing of the city's sewage, whether in the Chicago river or the Calumet, must be solved without delay.

American Congress of Tuberculosis.—The second annual meeting of the American Congress of Tuberculosis will be held at the Grand Central Palace, New York, on the 15th and 16th days of May, 1901, in joint session with the Medico-Legal Society of New York. It is proposed to open a museum of pathology, bacteriology, and public health, with an exposition of electrical and other appliances used in any way in the arrest or treatment of the disease. The medical profession of all countries is invited to contribute papers to be read before this congress. The papers should be forwarded to the secretary on or before the 15th day of April next, and the title of the papers forthwith, to facilitate classification, as the time is short.

North Brother Island Hospital.—Complaints to the newspapers made by a former patient of the small-pox hospital, as to improper treatment while there, were proved by recent inspections of the health board to be without real foundation.

Obituary Notes.—Dr. William Channing died in a Boston hospital on March 19th. The deceased was the son of a Boston medical practitioner. He graduated from Harvard in the class with Dr. Edward Everett Hale. Afterward he took his degree in medicine at the University of Pennsylvania and before settling down to practice in Washington, studied abroad. Dr. Channing was a many-sided man, with an especial aptitude for invention. He invented a fire-alarm telegraph, a marine railway, and a number of appliances for use in medical electricity. He was the author of the first books published on this subject. The hand receiver for the telephone, now in use, was his invention, the Bell people having purchased it from him. Dr. Channing was a prominent leader in the abolition movement.

Dr. Jacob E. Hoffer died at Columbia, Pa., on March 22d, at the age of seventy-five years.

Dr. Edward Clarence Fraser died at Philadelphia on March 21st, at the age of sixty-one years. He was a graduate of the University of Maryland and of Jefferson Medical College.

Dr. Richard K. Valentine, fifty years of age, a well-known homœopathic physician of Brooklyn, committed suicide on Friday night, March 22d, at his home, 190 Lincoln Place, while suffering from mania caused, it is said, by grippe.

Dr. George Wren, the house physician of St. Vincent's Hospital, died there on Saturday, March 23d, of typhoid fever. He was born in Bridgeport in 1873, and in 1899 graduated from the Bellevue Medical College, going at once to St. Vincent's Hospital, where he was appointed house physician in January.

Dr. John Henry Hobart Burge, 132 Montague Street, Brooklyn, died on Sunday, March 24th, of heart disease, aged seventy-seven. He is said to have founded the first hospital in San Francisco, in 1849. Dr. Burge was consulting physician at the Long Island College Hospital and St. John's Hospital.

Progress of Medical Science.

Medical News, March 23, 1901.

An Interesting Case of Splenic Anæmia.—Herbert Maxon King reports this case. The patient was a woman aged forty years, born in England. Her mother died at the age of fifty-eight, of an "obscure trouble in the left side." The patient had never lived in a malarial district and gave no suggestion of syphilitic taint. She stated that she was always perfectly well until July, 1899. At this time, in order to relieve constipation, she took some sample pills, after which she had a severe diarrhœa and passed, at times, considerable blood. Her friends stated that for several years she has had a "peculiar, pale-yellow color." She was not emaciated. She complained of griping abdominal pain, diarrhœa, and extreme prostration. There were puffiness under the eyes and œdema of the lower extremities. She had a peculiar, yellowish pallor. The abdomen was not prominent. Palpation of this region did not elicit pain. The liver was not perceptibly altered in size, shape, or feel, although the left lobe was palpable. The spleen, enormously enlarged, retained the contour of a spleen, even to the notch in the anterior border. It filled nearly the whole left half of the abdomen. Palpation of this mass did not cause pain. The urine was of a low specific gravity, deficient in salts. On October 12th, blood examination gave the following results: Quantitative: red corpuscles, 875,000; leucocytes, 3,150; hæmoglobin, .15 (von Fleischl); color index, .86. Differential computation of leucocytes: Small lymphocytes, 22½ per cent.; large lymphocytes, 8 per cent.; polymorphonuclear neutrophiles, 61 per cent.; eosinophiles, 0; transitional forms, 4½ per cent.; myelocytes, 4 per cent. Qualitatively the blood evinced destructive changes of a character more profound than the author has ever noted in any condition except that of pernicious anæmia. There was marked poikilocytosis, as well as polychromatophilia, macro- and microcytosis. In counting 200 leucocytes, there were noted nucleated red corpuscles as follows: Normoblasts, 2; megaloblasts, 13; and other anomalous forms, 5. The splenic blood differed in no essential feature from the peripheral blood. The patient died the following December, and autopsy was unobtainable.

Cerebrospinal Meningitis (Weichselbaum, Jaeger) Treated by Repeated Lumbar Puncture.—By Henry Koplik.

Retrospects and Prospects in Genito-Urinary Surgery.—By Reginald Harrison.

Vertigo; a Stomach Lesion.—By Martin A. H. Thelberg.

Drainage in Abdominal Surgery.—By J. W. Long.

New York Medical Journal, March 23, 1901.

Emphysema of the Eyelid from Nasal Causes.—By Beaman Douglass. The cases specially mentioned are those arising from ethmoidal causes. In order to avoid the accident mentioned in the title, Douglass lays down the following rules for operation for the removal of ethmoidal caries: (1) As much as possible avoid the use of the curette, for it is the curette which is responsible for much of the traumatism occuring to the lamina papyracea. Much better work can be done by the use of the alligator forceps or some kind of cutting forceps having a small, blunt edge, which is less apt to perforate, and which will with equal success drain pus, or remove polyps as well as the mucous membrane lining the ethmoid cells. This forceps is very much more satisfactory than the curette in cutting away the thin layers of bone which form the walls of the ethmoid cells. (2) Another rule is, never to amputate any part of the middle turbinate, as it forms a very important guide along which an operation may be carried out. When it is remembered that the upper part of the middle turbinated body forms the inner wall of the ethmoid cells, it can readily be appreciated that by working carefully along the outer side of the middle turbinate—that is, the side away from the septum—the instrument must in each instance perforate the ethmoid cells; first, those which are anterior, and later, the posterior cells. In this way it is possible to open the ethmoid cells in the immediate neighborhood of the middle turbinated body, without working too near the orbit. This valuable guide will often prevent our entering either the orbit or the brain cavity. If subsequently it becomes necessary to remove this turbinate, it may be taken away after the ethmoid operation.

Infective Sigmoid Sinus Thrombosis.—C. R. Dufour gives a general description of the condition and the history of a personal case. His patient was a man aged forty-five years, with an ear discharging since childhood. The discharge ceased, hemicrania appeared, he became stupid, was chilly all the time, and the light hurt his eyes. These symptoms continued for several days, when he had a pronounced rigor followed by copious sweating. Tenderness was found in the posterior cervical triangle, with pronounced occipital œdema, beginning neuroretinitis, and a fluctuating temperature. The mastoid antrum was opened, cleaned out, the sinus exposed, and about a half an inch of it was found thrombosed at its knee; a portion only of the bony surroundings was necrosed, and was removed. The sinus was compressed above, opened, the thrombus removed, and the vessel curetted; the loss of blood was not great. The sinus was closed and the patient treated according to the method described. The lungs were not involved and there were no metastatic abscesses. The clot had not disintegrated; the microscope revealed streptococci and staphylococci. The patient made an uneventful recovery. It was a case in which the system was not overwhelmed with septic infection before operation. The fundus of the eye cleared up, and sight was normal in about eight weeks.

Some Retrospects and Prospects in Genito-Urinary Surgery.—Lecture by Reginald Harrison. The lecturer pays a high tribute to the work of Bigelow, of Boston, on litholapaxy and to that of White, of Philadelphia, with reference to the operation of castration for enlarged prostate. He thinks that the time may come when it will be possible to open the capsule of the kidney and relieve tension, thereby lessening the danger of chronic changes from the pressure of inflammatory exudation. As questions pertinent to this proposed intervention, he submits the following: (1) To what extent may kidney tension, as seen in kidney congestions, be responsible for permanent structural damage to these organs, which may ultimately result in their chronic degeneration, as observed in some forms of Bright's disease? That is to say, is there such a condition in pathology, to coin a term, as pernicious renal glaucoma? (2) Under what circumstances, if any, is the removal of tension by a surgical proceeding expedient and justifiable?

The Pathology of Intra-uterine Death.—A continued article by Neil McPhatter.

The Physical Examination of the Stomach.—By M. I. Knapp.

The Boston Medical and Surgical Jour., March 21, 1901.

Bubonic Plague.—Joseph J. Curry reports a number of cases occurring in Manila from January 1 to June 30, 1900. The most satisfactory method of diagnosis is the microscopical examination of the contents of a recently swollen gland, removed by aspiration. The plague bacilli occur in large numbers in the glands, even early in the disease. Some cases of the plague simulate malaria very closely. The examination of the blood fails to reveal the malarial parasite, and the blood early shows a marked leucocytosis. It was noticed that the right femoral and right inguinal glands were usually the first to enlarge. No wounds of the extremity were found, which were likely to be the point of entry of the infection. It was common, however, to find skin lesions involving legs and thighs. Dhobie itch is common, and the crotch is a favorite site: scratching may have introduced the bacillus. As most people are right-handed, it is possible that they scratch the right thigh more than the left.

Puerperal Insanity.—Arthur C. Jelly has found, by consulting the medical records of the Institutions' Registration Department of the city, that two hundred cases of puerperal insanity occurred from 1872 to 1900. From an etiological standpoint, cases can be divided into two groups: in the first the puerperal conditions appear to be the sole cause of the insanity—as in cases due to sepsis, exhaustion, perhaps to auto-intoxications. In the second group, predisposition existed and the puerperal state opened the door. Tuberculosis, epilepsy, profound hysteria, alcoholism, are all predisposing causes. The prognosis as to life is good. Recovery is stated to occur in from seventy to eighty per cent. of the cases in asylums. Physicians should be on the alert to recognize conditions favorable to insanity, and try to prevent it by hygienic measures. The author gives directions for treatment of the insanity.

Meat Rations in the Tropics.—P. R. Egan, surgeon of the United States army, contradicts the prevalent idea that meat should not be eaten in the tropics. To argue that because the poorer inhabitants of a country live on a certain food, that is the proper food to be taken in that country, is illogical, since they eat only what they can afford to get, and often suffer from starvation. The writer has found that tuberculosis and anæmia abound in Porto Rico where the people live on rice, beans, maize, dried codfish, and fruits. The people in the towns use meat and are far healthier.

Vomiting of Pregnancy; Suspension of Pregnant Uterus; Extra-uterine Pregnancy; Operation for Fibroids.—By J. Oswald Vogel.

A Case of Retroperitoneal Lymphangiosarcoma; Operation; Recovery; no Recurreuce after Two Years.—By J. B. Lund.

Jour. of the Amer. Med. Ass'n, March 16 and 23, 1901.

The Study of Anatomy.—Lewellys F. Barker thinks this subject could well be treated under two headings: (1) What does the science of anatomy include? (2) How can the study of anatomy best be prosecuted? And he devotes the present paper to the consideration of the former. Anatomy is not simply a descriptive science; the study of it as a preparation for practical medicine and surgery represents only one side of its interest and usefulness. The author then gives an interesting account of the history of anatomy, which to-day stands, in the opinion of many, practically complete and incapable of further progress, as far as skill in dissection and anatomical description are concerned. But the process of gathering facts is not all—they must be classified. The physiological viewpoint in anatomy must be considered. Closely connected with this is the mode of consideration of the surgical and topographical anatomist. Comparative anatomy and embryology together constitute morphology, and in this we recognize the part of anatomy which makes it truly worthy of being called a science. Two other phases which have been only recently extensively cultivated, are histogenesis and comparative histology. By histogenesis is meant the study of the development of the individual tissues, including the individual cells. By comparative histology and cytology are meant the comparative microscopical study of the various tissues and cells through a series of animals. As a crowning-piece to the whole system of anatomical study, experimental morphology must be recognized. The subject is too wide to be mastered in all its details, even when a whole lifetime is devoted exclusively to it.

General Bodily Resistance as a Factor in Nose and Throat Disease.—Frank Louis Stillman believes that it is most important for the physician to guard his patient against repeated attacks of illness. The majority of patients coming to the throat specialist are chronic sufferers, and these patients are very hard to cure by medication of any kind. Chronologically, at least, heredity has more influence upon bodily resistance than anything else. Physical types are transmitted. There are certain patients with especial susceptibility to nose and throat diseases. The writer believes that in regard to the reflexes caused by pressure points within the nose the general system is more at fault than the nose. The treatment of the nose and throat should also include general remedies. A thorough investigation of habits and hygiene should be made if the treatment of the case is to be intelligent.

The Amount of Myopia Corrected by Removal of the Crystalline Lens.—Edward Jackson states that, in myopia due to excessive corneal curvature, the removal of the crystalline lens would cause substantially the same optical effect as it would in the emmetropic eye—about 11 D. of change as measured at the cornea, or 12 to 13 D. as measured by a concave lens placed in the usual position for spectacle lenses. In myopia due to excessive refractive influence of the lens, after removal of the lens the eye would be left hyperopic about 11 D. measured at the cornea, and would require a convex 10 D. lens. In myopia due to increased length of axis, the optical effect of removal of the lens, as measured in diopters, increases in direct proportion to the increase of the axis, either at the cornea or at the usual position for correcting lenses.

Astigmatism, its Detection and Correction.—H. Bert Ellis says that the methods of detecting this trouble are both subjective and objective, but the best results come from using both methods in conjunction. The writer does not care for the ophthalmoscopic method. The subjective test is the trial lens. Skiascopy or retinoscopy is probably the most accurate method of measuring the total amount of astigmatism. As to the correction of astigmatism, just so much of the error should be corrected as comports with comfort after a few days' exercise with the correction. The writer emphasizes the value of spectacles *versus* nose glasses.

Diagnosis and Prognosis of Ear Disease.—B. Alex. Randall declares that prognosis in ear disease is of vital importance to the patient, if not to the surgeon. Almost every diagnosis is based upon the anatomy and physiology of the parts. Unaided, as well as aided, sight and touch are most important. The writer then speaks of the speculum, watch and voice tests, tuning-fork, Galton's whistle, bone conduction, and the Politzer test. The history of the patient should always be considered, but more valuable facts will often be obtained by objective methods. Anterior and posterior rhinoscopy should be practised. Response to inflation and pneumatic massage should be noted.

Quantitative Tests for Proteolysis.—A. L. Benedict notes the neglect of the subject of tests for stomach proteids, in works on diseases of the stomach. He then briefly reviews the physiological function of the stomach. On the whole, phosphomolybdic acid has proved, in the writer's experience, the most satisfactory precipitant of peptone—the result being very bulky. The only substances likely to cause a confusion in using phosphomolybdic acid as a test for peptone in chyme are alkaloids. These could not be present in the stomach in sufficient quantity during life to interfere with the test for peptone.

Systemic Factors in Catarrhal Deafness.—Sargent E. Snow states that chronic non-suppurative inflammation of the middle ear is most difficult to treat. The majority of patients are chronic sufferers. There are systemic factors which should be particularly emphasized: (1) A sluggish skin reaction; (2) low vital forces; (3) torpid liver; (4) a lack of proper exercise. The writer approves of cold baths and friction. The general system should be toned up, the liver kept active, and a proper amount of exercise taken. The otologist should pay special attention to the rules of hygiene and should insist on their observance by his patients.

The United States Pharmacopœia of 1900.—Joseph P. Remington states that the decennial convention which assembled on May 2, 1900, in Washington, held a very successful meeting. The officers represented different sections of the country. Various important changes are to be made. No compound or mixture is to be introduced if its composition or mode of manufacture be secret. The average approximate dose for adults, and sometimes for children, is to be stated. This volume will probably be published within three years.

The Pharmacologic Assay of Drugs and its Importance in Therapeutics.—E. M. Houghton declares that, in the absence of pharmacological assay, great variation exists in the strength of certain drugs. Some of the most powerful poisons known, belong to the class of drugs which do not admit of chemical assay. The writer then gives illustrations of variation in the strength of drugs in the open market.

Treatment of Atrophic Rhinitis by Electrolysis, and Some Experiments to Determine the Efficiency of Needles of Different Metals.—By Carolus M. Cobb.

"Ureine" Experiments to Determine the Truth of the recently Announced Discovery by Moor of the True Cause of Uræmia.—By John Weatherson.

A Case of Combined Gastric and Aural Vertigo, with a Discussion of the Pathology of Such Cases.—By G. W. McCaskey.

Philadelphia Medical Journal, March 23, 1901.

A New Treatment for Tuberculous Glands of the Neck with Minimal Scarring Involving a Method of Sterilizing a Tuberculous Region through the Lymph Channels.—G. Betton Massey describes his method as follows: A small opening is made through the skin and into the gland by a narrow bistoury, under a chloride of ethyl spray, and into the opening is thrust a sliver of amalgamated zinc to act as an anode, not insulated, of a weak galvanic current—1 to 3 milliamperes—which is turned on gradually and maintained for a few moments, to cauterize the tract and keep it patulous for the treatment proper. When the tract has received a sufficient impregnation with the mixed oxychlorides of zinc and mercury thus developed, to keep it patulous for a few days, the zinc electrode is withdrawn and an insulated gold electrode about the calibre of a piece of No. 18 wire is inserted, its point having previously been amalgamated and made to hold as much mercury as possible. This instrument is left bare for one-quarter of an inch from the point only, in order that all the current action shall be expended within the gland, the remainder of the instrument being insulated with fused hard-rubber or fused shellac. From 2 to 10 milliamperes is now turned on and maintained for ten minutes, or until all the mercury

has been dissipated from the gold surface, after which a piece of absorbent cotton or lint is placed over the opening, topped by a piece of plaster; the patient receives an application at intervals of two or three days. Cocaine may be used to deaden the slight pain. Thus the tubercle bacilli are destroyed, while often some of the gland tissue is left. The scar left is a mere point.

Duchenne-Erb Type of Upper-Arm Palsy following Multiple Neuritis.—D. J. McCarthy reports this case, which represents the double etiology of alcohol and lead in the production of multiple neuritis. Under rest, galvanism, and small doses of strychnine, the patient continued to improve, and at the end of three months presented the clinical picture of the so-called Duchenne-Erb type of combined shoulder paralysis. To this was added extensor palsy of both forearms, producing bilateral wrist-drop. The paralysis and sensory changes in the lower extremities in this case followed the alcoholic type. The intense wasting which occurred about the shoulder girdle was probably due to both the alcohol and lead. The combined effect of lead and alcohol on the nervous system could be differentiated with especial clearness in the present case.

The Clinical and Pathological Relations of the Chronic Rheumatic and Rheumatoid Affections to Acute Infective Rheumatism.—By A. E. Garrod. The rheumatic poison, says the writer, may smoulder for months or even years, breaking out at times in an acute attack. Between attacks a true rheumatic cachexia is developed, so that the relation of the chronic form to the acute manifestations of the disease is not hard to understand. When we come to the cases grouped under the heading of "rheumatoid arthritis," the problem is much more difficult, for we are not yet assured of the correctness of some of the current views as to the exact nature of this latter affection. This term may cover more than one disease, for not all the cases are of a rheumatic nature. Assuming that there are several forms of rheumatoid arthritis, it is quite possible, and even probable, that they differ entirely in their pathology, and that a theory which is true for one form may be wholly incorrect as far as another is concerned. The nodular or senile cases, with their slow progress and essentially chronic characters, present many features which suggest that the lesion present is of the nature of a degenerative or trophic change in the joints, comparable to the degenerative changes met with in other structures. Such a view of its nature receives support from the striking resemblance of these articular lesions to those met with in the joints of sufferers from certain nervous diseases such as locomotor ataxy and syringomyelia. In these latter cases, at any rate, there is nothing to suggest a rheumatic origin, and it is in these that the effects of mechanical influences are most marked.

The Treatment of Tuberculous Peritonitis.—Clinical lecture by I. Burney Yeo. The lecturer states that he has seen good results follow the internal administration of iodine and creosote, and the application to the surface of the abdomen of an ointment made up of iodoform and cod-liver oil in equal parts. The best results are obtained in the early stages, and in those in which there is more or less ascitic fluid. In these there is no matting of the intestines or shrinking or adhesion of the mesentery, but in advanced chronic cases, with induration of the various intestinal coats, adhesions of the coils of bowel to each other, large tuberculous masses and caseous mesenteric glands, neither surgical nor medical treatment offers much hope for recovery. Yeo believes that if iodoform is rubbed into the skin of the abdomen in a young person, it probably rapidly enters the blood, and if its use is persisted in, it is continuously eliminated in the secretions, including the secretions of the serous cavities. It thus comes in contact with the seat of the tuberculous deposit.

An Address on the Causation of Cancerous and Other New Growths.—J. George Adami states that whatever the origin of the tumor proper, however it is started, what makes the tumor is the assumption by the primary cells of that tumor of the habit of growth in place of the habit of work, and according to the extent of this replacement do we get the various grades of tumor formation, from the most benign to the most malignant. He also believes that that line of research is most valuable which lies in the direction of testing various methods of arresting the growth of the tumor cells without injury to the organs in general. But he believes the greatest benefit to the patient and the greatest satisfaction to the surgeon will consist in the recognition and removal of malignant tumors at the earliest possible date—and even the removal of benign tumors before they have taken on possible malignant characters.

Digestion Leucocytosis in Cancer of the Stomach.—Carstairs Douglas believes that digestion leucocytosis is a broken reed on which to lean in the diagnosis of cancer of the stomach. He thinks that, as Marchetti has recently said, digestion leucocytosis essentially depends on the digestive and absorptive powers of the stomach, and that it may or may not occur in cancer of the organ, according to the degree of impairment of its functions. The presence of the phenomenon is probably of more value in excluding cancer than is its absence in proving the existence of the disease.

A Case of Diffuse Scleroderma.—Robert Bleasdale reports the case of a man aged twenty-three years, who was suffering from well-marked diffuse scleroderma. Five years before, having been previously healthy, he began to be troubled with rheumatism in the hands and feet, with considerable swelling about the knuckles. After this had gone on several weeks, the skin on the arms and legs began to grow hard and tense. This condition gradually spread to the face and trunk, and his whole appearance was very typical. He finally developed phthisis and died.

Concerning the Pathogeny and Pathological Anatomy of Pterygion.—Catherine Trapesontzian concludes that the pterygion comes most often from the pinguecula, an affection characterized by hyaline degeneration of the elastic and connective-tissue fibres, and by collections of hyaline substance between the fibres more or less normal. The proof of this is furnished by the presence of "débris" of the pinguecula that is found in the pterygion. The hyaline degeneration is not limited to the débris, but implicates little by little the rest of the hyperplastic and hypertrophic tissue. The elastic fibres are equally hypertrophied and degenerated, but their number does not appear strikingly increased. Collections of free hyaline substance exist without a doubt, but play a secondary rôle. It is this substance that Weigert considered solidified fibrin. It does not give us the characteristic reaction for fibrin. There is probably in the tissues a certain quantity of serum exuding through the vascular walls. In other cases the pterygion develops without being preceded by a pinguecula. The morphological characteristics of these pterygions, developing in different ways, are the same. The pinguecula signifies a profound alteration of nutrition of the tissues and changes their reciprocal relations. The conjunctiva becomes less supple, less elastic, and consequently more passive; it tends to preserve the abnormal

position which is forced upon it. In every case the process passes below the epithelium of the cornea.—*Revue Médicale de la Suisse Romande*, February 20, 1901.

Certain Morbid Phenomena of Second Infancy, in Relation to a Toxic Dyspepsia of Alimentary Origin.—Sevestre states that it is not rare to observe in the course of second infancy, generally from seven to fifteen years, a group of morbid phenomena which at first sight may appear alarming. At times they make one fear meningitis, cardiac trouble, etc., but if carefully studied they will be discovered to be of alimentary origin. The most common symptoms of these troubles are headache, generally frontal, insomnia, nightmare, palpitation of the heart, fever, and vomiting. These children will often be found to eat very rapidly, without proper mastication, while they drink abundantly during meals. After the indulgence of these habits for some time, the stomach becomes distended and less active; the colon is often distended with gas; the liver is generally enlarged, and constipation is present; the latter sometimes alternates with diarrhœa. These conditions produce toxins which are absorbed, thus giving rise to the untoward symptoms. The bad habits of the child should be strictly corrected. The régime should be carefully revised; proper mastication must be insisted upon. A tonic often serves a good purpose. Massage for atony of the intestine is indicated. Hydrotherapy must not be neglected, and finally the child must be out in the open air as much as possible, even though books have to be laid aside. —*Journal des Praticiens*, February 23, 1901.

Solid Tumors of the Ovary.—Phocas declares that solid tumors of the ovary are relatively rare. In the beginning there are in general painful phenomena. With the functional signs a tumor is found, varying in size from a nut to a mandarin orange, movable, situated at the side of the uterus, not painful, or but slightly so, and uniformly hard. During the period of growth the functional signs vary; among them are menstrual troubles. The evolution of these tumors is slow. Clinically, there are two large classes of solid tumors of the ovary: benign and malignant. After ablation of the tumor, histological examination will give an exact diagnosis, which is so frequently uncertain before operation. According to Dartigues, every solid tumor of the ovary, whatever may be its histological nature, should be removed.—*Le Nord Médical*, March 1, 1901.

Adenomata of the Suprarenal Bodies. — R. Oppenheim believes from his study of this subject that the distinction of suprarenal adenomata into fatty and pigmented adenomata is fully justified. The first are due to the proliferation of the cells of the median cortical zone, and the hyperplastic cells are always the seat of an abundant fatty infiltration. The second come from the hyperplasia of the elements of the zona reticularis. The protoplasm of the cells which constitute them does not contain fat, but is infiltrated with pigment, in such large quantities perchance, as to hide the nucleus and completely destroy the cell. The adenomatous capsules, like the normal capsules, can be the seat secondarily of diverse pathological processes (tuberculosis, hemorrhage).—*Bulletins et Mémoires de la Société Anatomique de Paris*, December, 1900.

Berliner klinische Wochenschrift, March 4, 1901.

Stramonium Poisoning.—E. Friedlaender gives the history of a man aged forty-four years, who was a sufferer from asthma. He was recommended to try a certain cure which consisted largely of dried leaves of stramonium, but by mistake he took it as a drink, dissolving about 30 gm. of the remedy in three-quarters of a litre of tea, and taking of this fluid about 150 c.c. Two friends, who also drank some of the fluid, though a much smaller quantity, took fresh milk on discovering their mistake, and escaped with only vomiting and diarrhœa, without experiencing any of the constitutional effects of the remedy. Immediately on taking the draught the patient felt a severe burning in the throat, and soon became unconscious. On admission, one hour later, to the hospital, his face was slightly cyanotic; respiration was 50 per minute, there were some mucous râles in the chest, and the pulse was 96. He had recovered full consciousness, the pupils were dilated to a maximum, and there was a slight flow of saliva. He resisted for a while all attempts made to pass a stomach tube so as to empty that organ, but later permitted this to be done. Internally he was given coffee and a mild alcoholic stimulant. Under this plan of treatment he gradually recovered his normal condition, though the severe burning pain in the throat persisted for quite a time. He was discharged on the fourth day.

The Staining of Diphtheria Organisms.—Dr. Piorhowska believes it possible to demonstrate positively the existence of these organisms by staining-methods, and advises the following method as a means for bringing out the germ more sharply. From a culture of bacilli from fifteen to twenty-four hours old, grown at a temperature of 37.7° C. on either glycerin-agar or Loeffler's blood serum, dry cover-glass preparations are made and stained with methyl-blue for twenty to thirty seconds. Decolorization is effected by holding for five seconds in a three-per-cent. solution of HCl-alcohol, and the contrast stain is then effected by dipping for five seconds in a watery solution of eosin (one per cent.). The polar nuclei are by this method sharply stained, while the central portion takes a red color which is more marked than with the vesuvin stain commonly employed.

Rare Forms of Syringo-Myelia. — By Dr. de la Camp. Two clinical cases.

Deutsche med. Wochen., Feb. 28 and March 7, 1901.

The Treatment of Gangrenous Hernia (Conclusion).—W. Petersen is an advocate of local anæsthesia in these cases, and believes in wide resection of the diseased portion of gut. The form of local anæsthesia that gives the best results is Schleich's infiltration method, and its employment greatly facilitates the work of the operator and increases the patient's chances of recovery. The danger of post-operative shock and collapse is practically done away with, while all risk of inhalation pneumonia is obviated and the operator can take sufficient time to determine just how much of the intestine is so far damaged as to require removal, a thing not always possible when a poorly borne general anæsthesia demands a prompt conclusion of the operation. For the purposes of resection and anastomosis, the Murphy button represents an improvement of the greatest value, since it saves time and increases the safety of the operation. A point on which especial stress is laid, is the thorough emptying of the intestine before the suturing is begun. The author effects this by inserting into the diseased loop of bowel a stomach tube through which the gut is irrigated with hot saline solution, the tube being gradually pushed in to its full length. This washing may take considerable time, and is most advantageously performed when the operation is being done under local anæsthesia, when the relief attending the clearing out of the distended bowel is so great that the patient gives little heed to the other details of the operation. Whenever there is any suspicion of lost vitality in the affected coil of intestine, either primary resection or exposure in the wound for observation is indicated, and the artificial anus is an emergency procedure to be resorted to only in collapse or extensive perihernial inflammation. When gangrene is known to be present, primary resection under local anæsthesia is the operation indicated.

Experimental Studies in the Heredity of Tuberculosis.—F. F. Friedmann, in a preliminary report, details the results of some experiments tending to show that direct tuberculous infection of the embryo may occur wholly from the paternal side and without any intervention on the part of the mother. The two ways in which transmission of the disease from the parents to the fœtus can take place are (1) through the placenta, *i.e.*, through the maternal blood stream, and (2) at the time of conception, through infectious sperm. That the first of these is possible has already been adequately shown in both animals and man, while to prove the possibility of the second mode of transmission it must be demonstrated that tuberculous semen may contain active tubercle bacilli and that these are capable, unaided by maternal factors, of entering the ovum. It has already been found that, even in the absence of genital localization, those affected with tuberculosis may have the bacilli in the semen, but proof of the second requirement has heretofore been entirely wanting. The author injected into the vaginas of rabbits, immediately after coitus, small amounts of diluted cultures of tubercle bacilli, and from six to eight days later prepared serial sections of the developing ova. In every instance it was found that the bacilli had penetrated into the interior of the ovum and were present in its cells, while in no case were any found in the mucous membrane of either uterus or vagina. This finding explains the fact that the offspring of a tuberculous father and a healthy mother may be infected, while the mother escapes unscathed, a striking analogy to what may take place in the transmission of paternal syphilis.

A New Test for Diacetic Acid in the Urine.—S. Lipliawsky has elaborated a test which is not open to the various objections that have been raised against the older reactions. Two solutions are required: a one-per-cent. solution of paramidoacetophenon and a one-per-cent. solution of potassium nitrite. A small amount of the first is mixed with one-half as much of the second, an equal volume of urine is added, and the whole well shaken with a few drops of ammonia. A few drops of the mixture are poured into a tube half full of concentrated hydrochloric acid, with a small amount of chloroform, and two to four drops of ferric chloride. The tube is now to be gently agitated, so

that no emulsification of the chloroform is produced; after one-half to one minute, the appearance of a violet tinge of the chloroform on settling will indicate the presence of diacetic acid. The reaction is extremely delicate, and the coloration produced remains permanent even after weeks of exposure to light, while it is uninfluenced by any drugs the patient may be taking.

The Disinfection of Typhoid Urine with Urotropin.—Schumburg says that previous investigators have found that under the use of this drug the cloudy urines full of typhoid bacilli, sometimes observed during convalescence, clear up and yield negative results to culture tests. In order to determine whether this was due to a real extermination of the bacteria or depended simply on an inhibition of their growth, he allowed threads infected with typhoid bacilli to lie in nutrient media, to which urotropin urine, obtained from a healthy individual, had been added. No growth took place, even after days of observation, but if one of the threads was removed and added to plain bouillon, immediate and vigorous growth occurred. The conclusion is that the urotropin disinfection is an unreliable safeguard and is not to be depended on.

An Inexplicable Ascultatory Phenomenon in an Infant.—Konrad Gregor describes the case of a child of three weeks, presenting a loud blowing systolic murmur over the whole of the right side of the thorax, anteriorly and posteriorly. The heart sounds were clear, and at autopsy a cheesy bronchopneumonia of the left lower lobe, with beginning degeneration, was found, together with miliary tuberculous infiltration of the rest of the lung, liver, and spleen. The heart was normal, and no cause for the murmur could be demonstrated.

The Identification of Human Blood by Means of an "Anti-Serum."—R. Stern publishes some further observations which tend to invalidate somewhat the specificity of the blood test recently described in the same journal by Uhlenhuth. The author corroborates the experiments of the earlier writer, but in addition has found that the blood of certain monkeys, and also albuminous human urine, give the same reaction.

Further Observations on the Value of Arloing and Courmont's Serum Reaction in Tuberculosis.—M. Beck and L. Rabinowitsch, after a further series of investigations, reiterate their former conclusion that this serum reaction has no specific value in tuberculosis, since it may be obtained both in healthy and tuberculous animals, and also in those affected with other diseases.

Atresia Auris Congenita.—Hunter Tod reports three cases, giving their histories in detail. In addition to the fifty-three cases mentioned in Ruedi's "Thesis" (1899) he has been able to collect fifty-four additional cases besides his own. A full reference table is given of these additional examples. He sums up our knowledge of the condition as follows: (1) The deformity is not hereditary and the cause is not known. (2) It occurs rather more often in females and is more often unilateral than bilateral. (3) One may get accompanying deformities, chiefly due to mal-development of the parts in connection with the first and second branchial arches. (4) The labyrinth is rarely affected. The hearing varies, but is present to some extent, though slight. Hearing-tests give practically the same results as those given in an uncomplicated middle-ear affection, but more marked. (5) Embryological, pathological, and clinical observations prove operation to be useless. (6) Something more perhaps can be done by careful non-operative treatment and by early and assiduous instruction in speaking and lip-reading.

The Question of Retaining the Skin of the Posterior Meatal Wall in the Radical Mastoid Operation.—Richard Lake commends the suggestion of Moll, that the meatal wall should be removed to facilitate healing and to save trouble. To this Lake assents, but finds a more logical reason in the following explanation: Very frequently patients return in a year or two after the radical operation, complaining of deafness, and the whole post-operation cavity is seen to be filled with wax. The explanation is simple: the ceruminous glands lie almost entirely in the posterior wall of the meatus. By any of the flaps in use in the operation these glands are transplanted from their normal situation to a position from which the exuded cerumen is unable to escape and from which it is no longer passed outward by the natural means. The delayed appearance of deafness is due in part to the large cavity there is to fill, and in part to the suspension of the glandular activity for some time subsequent to the operation.

Ear, Nose, and Throat Journals.

The Pneumatic Sinuses in the Sphenoid Wings.—Beaman Douglass has examined the relations of the pneumatic cavities of the sphenoid in two hundred cases and has found the following varieties to exist: (1) The great sphenoidal cavity may occupy only the body of the sphenoid, without extending into the small wing. This was found in thirty-one cases. (2) The greater sphenoidal cavity may occupy the body of the sphenoid, and other pneumatic cells, with a nasal communication, and lined with mucous membrane, may develop in the small sphenoidal wings. This was found in seven cases, and represents the frequency of the occurrence of a true sinus of the smaller sphenoidal wings. (3) The great sphenoidal sinus may develop in such a way that it occupies one-half the sphenoid body and, extending into the sphenoidal wing, may occupy it entirely or partially. This condition was found one hundred and sixty-nine times. (4) The great sphenoidal cavity may occupy the body and extend partly into the wing, in which case the whole or a part of the posterior ethmoidal cell may extend backward into the small wing of the sphenoid. The sinus of the small wing of the sphenoid in these cases is not developed. This condition was found forty times. (5) The greater sphenoidal sinus develops in the body of the sphenoid. The sinus in the small wings is also present. These sinuses of the smaller wings communicated on one side with the posterior ethmoid cell, and on the other side with the recessus spheno-ethmoidalis. It seems, then, that in 15.5 per cent. of all cavities examined the great sphenoidal sinus did not extend to the wings of the sphenoid, but was confined entirely to the body. In all of these cases the sphenoidal wings contained pneumatic cells, made so either by the development of a true sinus of the sphenoidal wing or else by the projection backward of a posterior ethmoidal cell into the small wing.—*Laryngoscope*, February, 1901.

The Use of the Tuning-Fork as a Test for Disease of the Maxillary Antrum.—D. A. Kuyk regards the tuning-fork as a possible test for determining the presence of pus in the antrum, especially in those cases in which the usual diagnostic methods fail to give definite results. The stem of the fork should be applied (after vibration is set up), over the first or second molar tooth. If the antra are free and clear, the tuning-fork will be heard with equal clearness on both sides and for a like duration. If one antrum contains fluid, the fork will not be heard so distinctly, perhaps very faintly, perhaps not at all—as occurred in one case—but if the opposite antrum is free the patient replies quickly and positively in the affirmative. Given another case in which the symptoms are obscure, but in which transillumination gives a shadow on the left side and none on the right, with subjective symptoms inclining one to suspect disease of the left side, the tuning-fork, placed on the left side will be heard louder and longer than on the right; the natural deduction will be that the left antral wall is thicker than the right, favoring thereby the better sound transmission, and thus almost conclusively eliminating this cavity as the offending structure. Such proved to be the case.—*Laryngoscope*, February, 1901.

Pseudo-Hæmoptysis of Naso-Pharyngeal Origin.—Ricardo Botey concludes an article on this subject as follows: Special literature does not sufficiently insist upon the occurrence of this form of hæmoptysis. Hemorrhages from the larynx, base of the tongue, and pharynx are relatively infrequent compared to nasopharyngeal bleeding. The source of the blood seen on the pharyngeal wall can be determined if one will clean the wall with a cotton carrier and then apply a fresh carrier behind the soft palate, when it will become at once covered with fresh blood. Bleeding in the vault is favored by the close attachment of the mucosa to the parts beneath and the comparatively poor protection of the epithelial layer. The use of the cotton as above described, together with the employment of the mirror, renders diagnosis easy. These methods of examination should never be omitted in cases of hæmoptysis when the chest reveals nothing abnormal.—*Annales des Maladies de l'Oreille*, etc., January, 1901.

Serous Cyst of the Auricle.—A case of this rare condition is reported by Richard Lake in the person of a man aged thirty-five years, who some four weeks before coming under observation had noticed a small, freely movable tumor in the region of the fossa of the antihelix of the left ear. In the course of the month it grew rapidly, measuring when first seen about one and a quarter inches by three-quarters of an inch. It was dusky in hue, not very tense, perfectly translucent, and not very definite at the edges. The exploratory needle withdrew a yellow fluid without suspicion of clot or blood in any form.—*Journal of Laryngology*, February, 1901.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEBACLE OF THE WATER COMPANIES, REVOLT OF THE RATE PAYER—ENTERECTOMY IN DIABETES—INTESTINAL SAND—PAINLESS PYONEPHROSIS—GYNÆCOLOGICAL SOCIETY—BIRMINGHAM INSTITUTE—DEATHS OF DR. FLEMING AND COL. MAITLAND.

London, March 8, 1901.

At last the London rate payers have roused themselves from their apathy. Alarmed by the proposed extortion of the water companies they have returned an overwhelming majority to the county council of the party pledged against monopolies.

The "moderates" fought the election on political lines and had all the advantages of the conservative party which is in the majority in the metropolis. But it was useless—the "progressists" were against monopolies and in favor of pure municipal government—their cry was "progress, not politics," and they swept the field. The conservatives say it was the pocket being touched that defeated them. Perhaps so, but the lesson was needed. It shows that even the London rate payers' apathy may be overcome.

After all, the water companies have done London a good turn by bringing forward their scheme at the psychological moment to advance the cause of good municipal government. If the majority fulfil their pledges, we may yet have pure water, clean streets, and other factors of a healthy city. The new metropolitan boroughs did good work in opposing the water companies, but it has been a costly business for them. Mr. Long made a blunder in ordering an inquiry into the proposed scheme, when he should simply have vetoed it. He has inflicted an injury on the rate payers, who are not likely to forget it—especially as he shows no disposition to safeguard their interests in future. He seems to think they ought to pay for the opposition they made to the companies. The election should open his eyes, unless he is to run the risk of wrecking the government, or at least making his new position untenable.

Intestinal sand has not attracted so much attention in this country as on the Continent. Whether it is less frequently looked for here, or does not occur so often, is not easy to say, but I am disposed, from all I hear, to think the former is the reason. Howbeit, a case was related at the last meeting of the Medico-Chirurgical Society by Sir D. Duckworth and Dr. Archibald Garrod. It occurred in a married woman aged thirty-three years, living in healthy surroundings, and was accompanied by intractable diarrhœa to the extent of six or eight loose motions daily. The colon and its sigmoid flexure were too palpable when empty, as if from thickened walls. The sand looked like a deposit of uric acid, was of a reddish-brown color, and fairly gritty—insoluble in cold and boiling liquor potassæ, readily soluble in boiling nitric acid. Under a low power of the microscope particles of various sizes and shapes were seen, of a brilliant reddish-brown hue, and translucent. Washed and dried in the air they looked like fine sand. The case was unusual, as there were none of the severe colicky attacks that have been generally met with in other instances.

Dr. Crombie thought the symptom less common here than in India, where intense colic was generally met with, the severity being in proportion to the amount of sand passed. Dr. Bokenham had met with a case accompanied by attacks of colic and diarrhœa.

The society's attention was then directed to surgery, in connection with two cases of enterectomy reported by Mr. Barker. They were brought forward as bearing on the limitations of operation, for both patients were glycosurics. One was a married woman aged fifty-eight years, the other a feeble old woman aged seventy-six years. In the latter case five and a half feet of small intestine were removed for gangrene; in the former, four and a half inches. Both patients recovered, showing that even in diabetics, when operation presents the only alternative to speedy death, the surgeon need not despair of a successful result. And yet how often have slight injuries in diabetics proved fatal!

Commenting on his cases, Mr. Barker said the first recalled what had been brought before the society concerning diabetic gangrene, in which condition good results had been obtained in spite of extensive arterial thickening. As to extensive excision of the bowel, he suggested that in younger persons who survived the operation a compensatory hypertrophy might occur to make up for the loss. Further, it seemed that resection was better tolerated the lower down in the intestine it was done.

The president (Dr. Pavy) said it was important to distinguish alimentary from other forms of glycosuria. In the former the condition could be removed by diet; in the latter, dangerous bodies, such as acetone, diacetic and oxybutyric acids, were present in the blood, along with sugar. These contraindicated all but imperative operations.

Sir Thomas Smith related a case in which a man, not previously known to be diabetic, accidentally scratched his finger, and within a week died of septicæmia with gangrene of all four extremities. Sir D. Duckworth remarked that in spite of antiseptics, surgeons must still be very cautious about operating on diabetics. Mr. Barker, in reply, said that in one case the glycosuria continued during the most important period of repair—a point of great interest.

At the Medical Society, Mr. A. Doran related a case of painless, calculous pyonephrosis, without fever. The patient was a woman aged thirty-eight years, whose husband had been subject to stricture and cystitis and who probably infected her. There was no history of rigors, colic, hæmaturia, or feverishness. The woman went about her domestic duties apparently in good health, although one kidney was converted into a bag of pus. She had noticed a swelling in the left side, and it ached when she had stays on but was comfortable when she was undressed. The lump was diagnosed as movable kidney and was not tender. On operation this kidney proved to be a cyst containing about a pint of pus. There was no trace of tubercle. The lowest calyces were blocked by a small rough calculus in the infundibulum. In one dilated calyx a piece of mulberry calculus lay loose. Mr. Doran thought it fortunate that the operation had not been delayed until adjoining structures had become involved, and he agreed with Noble, of Philadelphia, that removal of a suppurating kidney enabled its fellow to work better. The president (Mr. Morgan) thought the case almost unique in its absence of pain and fever, and asked about Mr. Doran's experience with boric acid in urinary sepsis. Mr. Butler-Smythe asked why the ureter had not been dropped back into the peritoneal cavity. Mr. Doran said in suppurative conditions he preferred to bring the ureter out of the lower end of the wound, as he had known a lumbar abscess to follow dropping the ureter back. It was different in non-suppurative conditions. He had seen boric acid followed by an improvement in the urine, but whether *post* or *propter hoc* he could not say. The next paper was by Dr. Lewers on fibroids of the cervix. He related four cases illustrating the differences between them and fibroids of the body of the uterus, and described the operations he performed. He is accustomed to adapt his operation to each individual case. Mr. Doran and several other speakers approved the measures which had been employed and congratulated Dr. Lewers.

At the Gynæcological Society, Dr. Mansell Moullin has been installed as president, and delivered an inaugural address in which he reviewed some operations as performed now and at the foundation of the society, seventeen years ago.

A "drawing-room meeting" was held on Friday at Stafford House (Duke of Sutherland's) which was practically the fourth annual meeting of the "Nurses' Total Abstinence League." Among the speakers who addressed the assembled nurses was Mr. Pearce Gould. He gave three reasons why nurses should be teetotallers: (1) Their work was hard, (2) they should always be ready for an emergency, (3) their work involved great nervous strain. All his experience convinced him that for hard work and to meet emergencies total abstinence was best, and the pernicious effects of alcohol were most of all marked in lessening the powers of men and women to bear nervous strain.

Mr. Treves has an article in the *Nineteenth Century and After* on the South African hospitals. He admires the patience and judgment of the commission, but he is not satisfied that their recommendations go far enough. He insists, as many have done, on the insufficiency of pay and allowances, the undermanning of the service, the amount of non-professional work thrown upon the surgeons, and the discouragement of ability and energy. He would have promotion by merit rather than by seniority.

Dr. Irvine, the consultant of the Birmingham Institute, has decided to vacate his invidious position instead of braving the Medical Council.

Among recent deaths are those of Dr. Fleming, of Glasgow, for a considerable period surgeon to the Royal Infirmary. He was only fifty-two, and had for some time been an invalid.

Lieutenant-Colonel Maitland, P.M.O., of the Somaliland expedition, was killed in action on February 16th. He had served in Egypt, India, and Burmah with distinction and received several medals. He was only forty-one years old.

SUPRARENAL EXTRACT IN HÆMOPTYSIS.

To the Editor of the Medical Record.

Sir: In your issue of March 16, 1901, there appears an article, namely, "The Use of the Suprarenal Capsule in Hæmoptysis," by William B. Kenworthey, M.D., in which he states that very little or no mention on the use of the

suprarenal capsule in hæmoptysis had been previously made

If the doctor will review the pages of your journal for November 17, 1900, pages 774 to 775, he will find an article by me, namely, "The Use of the Suprarenal Capsule in the Lower Air Passages," in which I mention the use of the suprarenal powder in sixteen cases of hæmoptysis, from various causes, without a failure.

SAMUEL FLOERSHEIM, M.D.

Reviews and Notices.

A PRACTICAL TREATISE ON MEDICAL DIAGNOSIS, for Students and Physicians. By JOHN H. MUSSER, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Fourth Edition, Revised and Enlarged. Illustrated with two hundred and fifty woodcuts and forty-nine colored plates. Philadelphia and New York: Lea Brothers & Co. 1900.

THIS book is certainly the outcome of a mass of practical work, the result of many years of bedside study. It is a pleasure to be able to say that nothing that the author states in his preface is overdrawn, and that this volume will meet with favor. To any one desiring modern views and methods of diagnosis, we commend this work. Consisting of over one thousand pages, it gives ample detail regarding the minutest points necessary in making a modern diagnosis. To the older physician and to the "rusty" physician, such books will be welcome. Rarely have we seen better illustrations, especially those bacteriological drawings.

SAUNDERS' MEDICAL FORMULARY. By WILLIAM M. POWELL, M.D., Author of "Essentials of Diseases of Children," Member of the Philadelphia Pathological Society, etc. Philadelphia: W. B. Saunders & Co. 1900.

THIS formulary has been before the medical profession for a number of years and is now entering upon its sixth edition, having been thoroughly revised and had added to it formulæ employing some of the more important recently discovered drugs.

The author in collecting these formulæ has drawn liberally from some of the most eminent authorities and specialists of this and other countries. A book of this character naturally has its limitations, and if literally followed, would undoubtedly be of little permanent value to any medical man of scientific aspirations. Its true purpose seems to be to furnish a working basis for the young physician just beginning the practice of medicine, who will realize the importance of making such variations in his prescriptions as each individual case shall demand. The book is well edited and handsomely bound in morocco.

PHYSICAL DIAGNOSIS OF DISEASES OF THE CHEST. By RICHARD C. CABOT, M.D. With one hundred and forty-two illustrations. New York: William Wood & Company. 1900.

THE author states that his book is intended for the use of students. It consists of over three hundred pages and is superbly illustrated. To one desiring accurate and detailed knowledge of the modern methods used for percussing, auscultating, and inspecting the thorax, nothing better could be advised.

A few points, such as the author styles well-worn myths, are prominently brought out. Thus are disposed of the errors in believing that the aortic second sound is normally louder than the pulmonic second, also that aortic regurgitant murmurs are usually best heard in the second right interspace, and that a hypertrophied left auricle can produce dulness and pulsation near the left sternal border, that systolic retraction at the cardiac apex means adherent pericardium, that epigastric pulsation denotes hypertrophy of the right ventricle, etc.

Other important points are muscle sounds, atelectasis pulmonum, and adherent pericardium. The radiographs are excellent. Thus we must say that this book is well adapted to instruct, and may also serve to refresh those in the profession seeking modern technique.

PORTRAITS OF THE NOTED PHYSICIANS OF NEW YORK, 1750–1900, with a Few Facts in the Life of Each, Collected and Arranged by WALTER GRAEME ELIOT, LL.D., Ph.D. Vol. I. 8vo, pp. 200. New York: American Biological Society. 1900.

To look upon the faces of friends, present and gone, is always interesting and instructive. This work may be viewed as a biographical album in which the subjects are well selected and very fairly treated as to respective merits. The result is not only due to the indefatigable efforts of the editor to be just and impartial to all, but also to the fact that eight of the most distinguished living surgeons have aided him in his selections. It is a pity, however, that this valuable contribution to the literature of its class is mainly intended for private distribution and public libraries. For purposes of reference it will be invaluable as a contribution to the medical history of New York during the period named. A page portrait is devoted to each individual, with a short account of his life and work. The most interesting sketches are those of the older masters in medicine and surgery who have long since passed away, and whose work was mainly done in the earlier years of the past century. In this class may be mentioned those of Wright Post, Samuel Burrowe, John Kearney Rodgers, Francis U. Johnston, John Jones, Samuel L. Mitchill, Samuel Bard, Alexander H. Stevens, David Hosack, John W. Francis, Augustus G. Eliot (the father of the author), Valentine Mott, and John C. Cheesman. Following these, in their chronological order, are the portraits of and sketches of Willard Parker, Gurdon Buck, W. H. Van Buren, Frank H. Hamilton, E. R. Peaslee, Alonzo Clark, George A. Peters, Henry B. Sands, J. Marion Sims, James R. Wood, and Alfred L. Loomis. Of the living men who form a becoming part of this distinguished company, there is scarcely one who does not deserve his place. Altogether the collection is the best and most representative of its kind that we have yet seen, and we heartily congratulate the author accordingly.

MODERN MEDICINE. By JULIUS L. SALINGER, M.D., Demonstrator of Clinical Medicine, Jefferson Medical College; Chief of the Medical Clinic, Jefferson Medical College Hospital; Attending Physician to the Philadelphia Hospital, and FREDERICK J. KALTEYER, M.D., Assistant Demonstrator of Clinical Medicine, Jefferson Medical College; Hæmatologist to the Jefferson College Hospital, Pathologist to the Lying-in Charity Hospital, Philadelphia; Assistant Pathologist to the Philadelphia Hospital. Illustrated; pp. 801. Philadelphia and London: W. B. Saunders & Co. 1900.

THE object of the authors in issuing this work is to combine in one volume the different specialties which are ordinarily scattered throughout separate books on bacteriology, urinary analysis, hæmatology, etc. In addition to the careful exposition of the technique in laboratory examinations, the main features of the etiology, pathology, symptomatology, diagnosis, etc., of disease are succinctly described. The introduction deals specially with symptomatology and semeiology in general, physical diagnosis, clinical bacteriology and laboratory methods, the last subject including the modern methods of examining the sputum, the stomach contents, the blood, the urine, and the fæces. The main bulk of the volume is taken up by articles on the infectious diseases, circulatory, respiratory, and digestive diseases, affections of the kidneys, blood, ductless glands, nervous system and the muscles, constitutional diseases, intoxications, sunstroke, and diseases due to animal parasites. The articles are well balanced, concise, conservative, yet thoroughly modern, and the practical points in differential diagnosis particularly good. The illustrations are useful and aptly chosen, some of them being in colors. The list of diseases is quite complete, including many of the most uncommon varieties.

TRAITÉ DE MÉDECINE. Deuxième Édition. Publiée sous la Direction de MM. BOUCHARD, Professeur à la Faculté de Médecine de Paris, Membre de l'Institut, et BRISSAUD, Professeur à la Faculté de Médecine de Paris, Médecin de l'Hôpital Saint-Antoine. Tomes VI. et VII. Paris: Masson et Cie. 1901.

IN these two volumes are discussed the diseases of the respiratory system, the authors being A. Ruault, E. Brissaud, P. le Gendre, A. B. Marfan, and Netter. The articles are: diseases of the nose and pharynx by Ruault, asthma by Brissaud, whooping-cough by Le Gendre, antepulmonary diseases and diseases of the pleura by Netter, and diseases of the bronchi, disorders of the pulmonary circulation, chronic pulmonary diseases, phthisis, and diseases of the mediastinum by Marfan. The articles are all worthy of their authors and are of the high grade which characterizes most of the contributions to this exceedingly valuable system of medicine. A comparison of certain of the treatises with those in the first edition shows that the revision has been very carefully done.

RHINOLOGY, LARYNGOLOGY, AND OTOLOGY IN GENERAL MEDICINE. By E. P. FRIEDRICH, M.D., Leipsic. Translated from the German. Edited by H. HOLBROOK CURTIS, M.D. Pp. 348. Philadelphia: W. B. Saunders & Co. 1900.

THE author's object has been to point out the "interdependence between diseases of the entire organism and affections of the nose, pharynx, larynx, and ears." His

purpose has been well accomplished. The correlation of diseases of these special organs with general systemic diseases is well brought out and clearly and admirably stated. The author has drawn the material for his excellent work from an extensive personal experience and from a masterly survey of the recent literature. A critical analysis of the special chapters is hardly within the scope of this notice, but the reviewer endorses the opinion of the editor that no specialist in this line can well afford to neglect a careful study of the work, nor any general practitioner dispense with reading a book so pregnant with data bearing upon the proper interpretation of the symptoms of general systemic disease.

Journal of the Boston Society of Medical Sciences. Vol. V., No. 5. Edited by Harold C. Ernst, A.M., M.D. 319 pages.

The present issue of the *Journal* contains a study of the bacteriology and pathology of two hundred and twenty fatal cases of diphtheria, by Drs. W. T. Councilman, F. B. Mallory, and R. M. Pearce. The study closes with an elaborate bibliography and with a series of finely executed plates. It is a creditable publication of a progressive society.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D., Professor of the Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia; Attending Physician to the Medico-Chirurgical and Samaritan Hospitals, Philadelphia, etc. Illustrated. Fourth edition; thoroughly revised; pp. 1,292. Philadelphia and London: W. B. Saunders & Co. 1900.

Although the preceding issue of this work appeared but little more than a year ago, the demand has compelled the publishers to bring out a fourth edition, which is in all respects a book adapted to the use of the general practitioner and student. It is eminently helpful in all its suggestions regarding diagnosis and treatment, and shows that the author is fully conversant with the difficulties which lie in the path of the family doctor. The articles are thorough, without falling apart from the weight of unimportant details which so often serve to confuse rather than instruct. This edition differs from the third in additions to and rearrangement of the text, while a few articles have been entirely rewritten. A thoroughly up-to-date and practical working volume like this cannot fail to appeal to the profession and gain a well-earned popularity.

Uric Acid as a Factor in the Causation of Disease: a Contribution to the Pathology of High Blood Pressure, Headache, Epilepsy, Mental Diseases, Paroxysmal Hæmoglobiuuria and Anæmia, Bright's Disease, Diabetes, Gout, Rheumatism and other disorders. By Alexander Haig, M.A., M.D. Oxon., F.R.C.P., Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women; late Casualty Physician to St. Bartholomew's Hospital. Fifth edition; with 75 illustrations; pp. 846. Philadelphia: P. Blakiston's Son & Co. 1900.

This well-known work, the fourth edition of which was issued about three years ago, again appears in an enlarged and enriched form. The author treats of the formation and excretion of uric acid, and deals with the problems with which this poison is associated, especially that of circulation. Headache, epilepsy, hysteria, asthma and bronchitis, alimentary gout, Raynaud's disease, anæmia, diabetes, heart disease, etc., are all studied carefully. He claims that the circulation is undoubtedly a truthful index of the amount of uric acid in the blood, and that by treating the patient with certain dietaries he can control almost perfectly the circulation and the conditions depending thereon. The book has numerous illustrations showing pulse tracings, the variations in the excretion of uric acid, etc., which make the text more readily understood.

A Practical Treatise of Materia Medica and Therapeutics, with Special Reference to the Clinical Application of Drugs. By John V. Shoemaker, M.D., LL.D., Professor of Materia Medica, Pharmacology, Therapeutics, and Clinical Medicine, and Clinical Professor of Diseases of the Skin in the Medico-Chirurgical College of Philadelphia. Fifth edition. Philadelphia: F. A. Davis Company. 1900.

Dr. Shoemaker has made a new departure in this revision of his well-known treatise on materia medica by issuing two distinct books, one the students' edition, which is the one before us, the other to be called the physicians' edition, which will appear shortly. In the students' edition only the drugs and preparations which are official in the British or the United States Pharmacopœia are treated of, except incidentally as they may be derived from one of the standard preparations, the consideration of the newer, and as yet unofficial remedies being reserved for the physicians' edition. The system of weights and measures employed is very properly the metric, though the equivalents in the old system are also given in parentheses. The work is one of the best of its kind, and it improves with each revision.

French Method. By François Berger. New York: 1900.

This little book of almost two hundred pages is designed to give elementary instruction in the French language, and contains some illustrations.

Gesundheitspflege im Kindesalter. Von Dr. Joseph Trumpp, Privatdozent für Kinderheilkunde an der Universität in München.

This is a practical guide, adapted for the mothers and nurses of infants. It deals with the hygienic and dietetic management of the same. It also speaks of school hygiene and gymnastic exercises. The author's experience will add to the value of this interesting volume.

Terapia delle Malattie dell' Infanzia. By Prof. C. Cattaneo. Milano: Ulrico Hoepli. 1901.

This pocket edition consisting of five hundred pages has just appeared. It deals with the treatment of infantile disease and the exanthemata. It is arranged alphabetically, thus: acne comes first, and vulvo-vaginitis and zona end the little book.

Eye, Ear, Nose, and Throat. By William Lincoln Ballenger, M.D., and A. G. Wippern, M.D. Series edited by Bern. B. Gallaudet, M.D. Philadelphia and New York: Lea Brothers & Co.

To the practitioner desiring details in the management of the commoner diseases of the eye, ear, nose, and throat, this book can well be recommended. It is superbly illustrated. Great care has been given to anatomical illustrations.

The Medical News 1901 Visiting List.

The list received is arranged for thirty patients per week. A thumb index makes it easy to turn to daily records, memoranda, obstetric engagements, operations, vaccinations, deaths, addresses, and cash accounts. The usual tables of doses, antidotes, etc., appear. The binding is in imitation alligator leather.

Food and Dietetics. By Robert Hutchinson, M.D. New York: William Wood & Company. 1901.

This book embodies a series of lectures given at the London Hospital, to which the author has added many practical points.

Although it is especially designed for students and practitioners of medicine, it is well adapted to serve as a guide to any one desiring an insight into foods and food products.

A great many practical points in the chemistry and physiology of foods are carefully considered. The illustrations, especially the tables and the numerous recipes (for example, those for both subcutaneous and rectal feedings) will be found especially valuable.

This book is very neatly printed on good paper, and the illustrations are excellent.

The Practice of Medicine: A Text-Book for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania, and Physician to the Hospital of the University; Physician to the Philadelphia Hospital. Second edition, thoroughly revised and in parts rewritten. Pp. 1222, with 127 illustrations, including colored plates. Philadelphia: P. Blakiston's Son & Co. 1900.

The author has taken the opportunity afforded by the demand of a second edition thoroughly to revise and enlarge his work. Like its predecessor, this edition shows the same clearness in description, the same good sense in treatment, for which Dr. Tyson is famous. The outcome of a long and busy career as a practitioner, laboratory worker, and teacher, this work cannot fail to please and beget the confidence of the reader.

As a working volume it meets all demands, being complete enough for practical purposes and yet not too exhaustive for the busy doctor. This issue shows additions in the articles on infectious diseases, nervous diseases, and diseases of the blood and vascular systems, which bring the work thoroughly up to date.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Sixty-second Regular Meeting, Held on Friday, March 1, 1901.

A. Alexander Smith, M.D., President, in the Chair.

A Case of Raynaud's Disease with Some Unusual Features.—Dr. Walter B. James presented this patient, a boy eighteen years old, a grocer's clerk, who had always enjoyed good health and whose family history was good, with the exception that his father suffered from asthma. Last December the boy accidentally shot himself in the right temporal region. The bullet was supposed to have passed through the brain and was extracted in the opposite left parietal region by a trephining operation. The patient made a good recovery and five weeks after the accident he left the hospital, apparently in perfect health. About a week later he began to suffer from very severe pains in both feet. He then noticed that his toe nails were falling off, and in a comparatively short time—two or three weeks—he had lost them all. The pains grew worse, and superficial ulcerations developed in the anterior third of both feet. These healed very readily, but at the same time he showed the typical symptoms of erythromelalgia involving both feet. On walking, or when the feet were held in a dependent position, they became flushed and he suffered from intense burning, boring pains which quite disabled him; the flushing and pains disappeared entirely when he resumed the recumbent position. Dr. James said he was inclined to regard the case as one of Raynaud's disease, with unusual manifestations. Although the bullet in its course through the brain passed near if not through the supposed centres for the feet and legs, the speaker said he could see no direct connection between the accident and the subsequent symptoms involving the lower extremities.

Dr. Henry F. Walker said the case presented by Dr. James was certainly interesting and the symptoms described were rather unusual. Whether they bore any relation to the injury of the brain which had been sustained just before their development he had no experience by which to judge.

Dr. Robert Abbe said that in the record of this case he thought it important that the track of the bullet should be carefully noted, although it was difficult now to see any connection between the injury itself and the subsequent manifestations. Possibly they resulted from some injury to the terminal fibres of particular nerve tissues or to parts of the lateral ventricles. The symptoms were strikingly like those of syringomyelia, which represented a lesion of the central canal of the cord which was practically a continuation of the lateral ventricles.

Dr. F. P. Kinnicutt said that it was difficult to trace any connection between the bullet wound of the brain and the development of the subsequent symptoms. The pathology of erythromelalgia was still obscure. The speaker said that about eight or nine years ago he had an attack of erythromelalgia, following influenza. The symptoms, which were quite typical, were confined principally to one leg. When the leg was held in a dependent position it became red and exquisitely painful. Dr. M. Allen Starr pronounced the case one of erythromelalgia. The symptoms persisted about three weeks and then disappeared entirely.

Dr. James, in closing, said the only explanation he had to offer for the occurrence of the symptoms after the accident was that the phenomena which we called erythromelalgia and Raynaud's disease and angioneurotic œdema were more or less closely allied, and it was quite reasonable to assume that, in the particular case under discussion, the shock of the injury was the determining factor in their production. In Dr. Kinnicutt's case the erythromelalgia followed an attack of grippe, which we knew left in its train various nervous phenomena. In another case of very pronounced erythromelalgia under the speaker's observation, the patient was a woman who, after her confinement, suffered from milk leg and subsequently underwent an operation for hemorrhoids. While recovering from this, she heard bad news from one of her children in the country, and soon afterward she began to suffer from erythromelalgia. The rational explanation in her case was that the combination of circumstances—the thrombotic leg, the operation for hemorrhoids, and the mental shock following it—were the causative factors in the production of the erythromelalgia.

A Case of Retained (?) Intubation Tube.—Dr. J. E. Traub presented, by invitation, a girl who was intubated on February 25, 1900, for the relief of acute laryngeal obstruction of diphtheritic origin. Nine days later the tube was removed, but it was necessary to reintroduce it at once on account of a recurrence of the dyspnœa. Two weeks later an unsuccessful attempt was made to remove the tube, and on April 10th Dr. Barker, of the Willard Parker Hospital, tried to extubate and failed. Further attempts at extubation were deemed unwise, on account of the nervous condition of the child and an intercurrent attack of bronchopneumonia. About three and one-half months after the primary intubation, the child was able to articulate fairly well, but her voice was still somewhat impaired. She was croupy at times and had a somewhat metallic cough. In order to decide the question whether the tube was still in the larynx, the child was submitted to the *x*-ray a few days ago. The resulting negative failed to show the presence of any foreign body in the larynx. In reply to a question, Dr. Traub said the girl had no trouble in swallowing.

Dr. Robert Abbe, after examining the negative, said there could now be no doubt that the tube was not in the larynx. He thought it had probably been swallowed and passed per rectum.

Some Fallacies in Therapeutics.—By Dr. George L. Peabody (see page 481).

Dr. Kinnicutt said that Dr. Peabody's paper was both interesting and timely. Many physicians, no doubt, were in the habit of using drugs the efficacy of which was entirely *nil* and based upon insufficient knowledge or upon experimental investigations regarding them.

Dr. Beverley Robinson said that while he had a certain amount of scepticism regarding the value of many drugs, he was not entirely in accord with the statements made by Dr. Peabody. The value of a certain drug could not always be accurately and positively gauged by laboratory research or animal experimentation. The facts stated by Dr. Peabody regarding certain drugs were no doubt based upon scientific research, but while science was one thing, art was another, and in the practice of medicine nothing could take the place of practical bedside observation. For example, Dr. Robinson said, he had great faith in the efficacy of oxygen inhalations in respiratory troubles and in anæmia, and as for creosote he knew of no single remedy which was more beneficial in catarrhal and other conditions of the respiratory passages. Of course, much depended upon the way in which drugs were given; the preparation and method of administering drugs should receive just as careful attention as the preparation and taking of our food. As regarded ergot, Dr. Robinson said that in spite of all that had

been said to the contrary, he still believed that the drug had a certain effect in arresting pulmonary hemorrhage.

Dr. Joseph D. Bryant recalled two recent cases in which gas was freely employed, one of œdema of the lungs, the other in which no form of pulmonary obstruction was present. The first case was that of a physician who was fully conscious while the inhalations were given, and who repeatedly made the statement that they comforted him and relieved his dyspnœa. In the second case the patient was unconscious and unable to express any approval, but several observers who were watching the administration of the gas, one of whom was a physician, were very certain that it exerted a salutary effect on the breathing. Personally, Dr. Bryant said, he had not been able to detect any beneficial effect on the pulse, respiration, or circulation from the use of the oxygen, in either one of these cases, although he had no doubt of the fact in the former. The anxiety on the part of all concerned to realize benefit from its use, no doubt prompted in many instances the ill-founded belief in its efficacy in unsuitable cases. Dr. Bryant said he had read somewhere that ergot was not effectual for the purpose of checking pulmonary hemorrhage, for the reason that the arterioles in the lungs were without nerve filaments.

Dr. Andrew H. Smith suggested that the reputation gained by the bitter tonics as appetizers perhaps rested upon the fact that people who took them before meals ate in order to get the bitter taste out of the mouth. With reference to ergot, the speaker said that Dr. Peabody had not overthrown the old belief that ergot stimulated the circular fibres of the arterioles and produced in that way a certain degree of anæmia of the capillaries. It would seem, therefore, that the drug ought to prove beneficial for the purpose of controlling capillary hemorrhage. In hemorrhages from arteries centrally located—as for example an intestinal hemorrhage in typhoid fever—ergot could only make matters worse by constricting the arterioles beyond the point of lesion. Dr. Smith said he agreed entirely with Dr. Peabody regarding the value of oxygen. When the quantity of atmospheric air which could reach the air vesicles was less than the amount required, oxygen was indicated, and would almost certainly give relief. That the gas possessed no great power in itself to produce superoxygenation, the speaker said he once demonstrated to his own satisfaction by the following experiment: Four mice were confined for four days in an atmosphere of pure oxygen, and in order that there should be no accumulation of the expiratory elements, a continuous stream of oxygen played into the vessel in which they were confined. During the period of their confinement they apparently suffered no discomfort, eating and sleeping naturally and behaving as usual, and when they were removed they were apparently in the same condition as when they were put in. This experiment, Dr. Smith said, illustrated the impossibility of making the blood take up an excess of oxygen by the mere fact of affording an excessive supply to the lungs. This was also shown in cases of poisoning from illuminating-gas; in such cases the inhalation of oxygen had no effect whatever.

Dr. Kinnicutt said that he had the impression that potassium iodide was beneficial in certain cases of asthma. We were apt to be led astray, however, regarding the value of a certain drug, by our polypharmacal tendencies.

Dr. Walker said that while it had been claimed as proved many times that mercury exerted no effect on the liver, still in cases in which there was inaction of the liver he had customarily used the milder preparations of mercury, and with decided apparent benefit. It certainly seemed to increase the flow of bile, whether by irritation of the upper intestines or by direct influence upon the liver tissue itself he did not know. With regard to potassium iodide, the speaker said he believed he had seen cases of asthma and emphysema with asthmatic elements, which were benefited by its use; otherwise, excepting in syphilis and as a diuretic, he had not found it of particular service. He had never seen any effect from it when given for the purpose of absorbing old inflammations or in meningitis. As a rule, the physician, as he practised longer, was more inclined to limit the number of drugs he used, and his chief guide was his personal experience. Dr. Walker said that a number of years ago, while travelling in California with a party of friends, the only medicine he had with him was an ounce of the tincture of opium, and he made this answer for all ailments which came up, including pneumonia and cholera morbus.

Dr. Charles Stedman Bull said he was entirely in accord with what Dr. Peabody had said regarding lithium and creosote. He was perfectly convinced, from personal experience, that lithium, in any of its various combinations, was of very little use in gout. Creosote in pulmonary tuberculosis was beneficial only in so far as it improved the patient's appetite and allayed gastric irritation.

Dr. Abbe said he did not agree with Dr. Peabody's statement that surgeons had entirely discarded boric acid. Personally, he used it more than ever as an antiseptic of a mild type, and its value was proved in this regard in purulent ophthalmia, in which its effect could be noted. It was equally good as an antiseptic in surgical work in the nasal cavity and mouth. Dr. Abbe said that while serving as a hospital interne he was instructed to get the effect of tannic acid as a hæmostatic in menorrhagia, by administering it in the shape of gallic acid (into which the former is supposed to be converted in the body). The drug was given in capsules, in gr. xx. doses every two hours, and in many cases it apparently proved effective. Ergot undoubtedly exerted a decided action upon the arterioles. This fact the speaker said he had seen beautifully illustrated by its effect upon the circulation of a cock's comb, which under the influence of the drug was seen to change in color very rapidly, shrinking in size and wilting down under its arterial contraction. Hence it would seem to be a rational drug to administer in capillary hemorrhage. Some forms of bronchorrhagia were of this type, hence the drug might have occasionally proved efficacious, and obtained a slight ground for popularity, though it would be useless in severer arterial bleeding in pulmonary cavities.

Dr. William M. Polk said that a few years ago, when oxygen was quite extensively employed in combination with ether as an anæsthetic, he noticed that it seemed to interfere somewhat with the coagulability of the blood. It apparently had a tendency to promote bleeding; at any rate, the hemorrhage could not be otherwise accounted for. In connection with the effect of drugs in general, Dr. Polk said that at one time, when he had the honor to teach materia medica and therapeutics, he had derived much comfort from a suggestion made by Dr. Smith that in the giving of drugs each individual must be judged by a separate physiological standard. This was undoubtedly true regarding many drugs. It was particularly true in the case of calomel. Some persons, especially those who were suffering from chronic malarial poisoning, could not get along without an occasional dose of this drug.

Dr. Andrew H. Smith asked whether Dr. Peabody would not admit that the circulation of the liver might be influenced by the use of mercurials, without admitting their property as cholagogues. If there was anything in medicine that we were fairly certain about, it

was that the hemorrhoidal veins were relieved in a measure by a good dose of blue mass. This seemed to indicate that the drug exerted some influence upon the liver, by acting upon its circulation if not by stimulating its function.

Dr. Peabody, in closing, asked Dr. Robinson whether his faith in oxygen as a remedy in anæmia was well founded. We knew that anæmia might be benefited without oxygen, by a great variety of drugs and conditions: by iron, by arsenic, by exercise, by rest, by diet, by intestinal antiseptics, etc. The oxygen was, of course, harmless, but its great expense should always be borne in mind. There could be no question as to its value in œdema of the lungs. There we had to deal with an obstructive condition. The speaker said he had seen immense benefit follow inhalations of oxygen in miliary tuberculosis, with its intense bronchitis; he had seen a patient blue and cyanotic from carbonic-acid-gas poisoning immediately relieved by it. In short, it was of enormous value in obstructive conditions. These included certain cases of pneumonia, emphysema, and cardiac trouble. As to the value of creosote in pulmonary tuberculosis, Dr. Peabody said he wished to limit his remarks to the internal administration of the drug. As to what it did by inhalation, he was not prepared to say; it might have some local effect on the pulmonary tissues, just as turpentine inhalations unquestionably exerted a beneficial effect in gangrene of the lung. As to whether creosote could have an antibacillary effect when taken internally was hardly worthy of discussion. It had to be in the strength of 1:4,000 in the blood in order to inhibit the growth of bacilli, and we could not give it in any such quantities. What it actually did was to improve the digestion of the patients; they could take food and cod-liver oil better and suffered less from indigestion. As to ergot, Dr. Peabody said his criticisms regarding its use had been confined to cases of pulmonary hemorrhage only. He freely admitted that it controlled capillary hemorrhage, in the intestines and uterus particularly, but it was absolutely useless in pulmonary hemorrhage. The capillary vessels in the lungs had no nerves and did not contract under the influence of the drug, and arterial pressure being raised by it, arterial bleeding was likely to be aggravated. Dr. Peabody said his remarks regarding potassium iodide had been misunderstood. He had said that this drug was decidedly beneficial in the treatment of asthma, but that it was of no use in emphysema, excepting when there was high arterial tension, when the potassium element might do good and possibly might relieve the bronchial spasm; but in old cases, without undue arterial tension, it was more likely to do harm. The drug, therefore, should not be given indiscriminately in emphysema. As regarded mercury and its effect on the liver, Dr. Peabody said that all he claimed was that the mild mercurials were really hepatic sedatives and did not increase the amount of bile formed in the liver; but they were of value in biliousness for the purpose of removing bile from the body, because they hastened peristalsis and caused the discharge of a large amount of bile per anum, much of which would otherwise be reabsorbed and go back to the liver. They probably did not regulate the circulation of the liver; in fact, we knew of nothing that would do that without influencing the circulation in general. Mercurials diminished the amount of bile secreted by the liver and hastened its elimination by the bowels.

Therapeutic Suggestion succeeds in night terrors, somnambulism, nocturnal incontinence of urine, and other pathological states of sleep. It also acts unless the subject is already under strong auto-suggestions, is hysterical or hypochondriacal.—Froemner.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 21, 1901.

Robert F. Weir, M.D., President.

The Modern Treatment of Gonorrhœa and its Complications and Sequelæ.—This was the subject for the evening's discussion.

Acute Gonorrhœa.—Dr. G. K. Swinburne took up the subject of acute gonorrhœa. He insisted strenuously upon the necessity for individualizing the treatment of this disease. The day had gone by when all urethral discharges were treated empirically; the differential diagnosis should be made with the microscope. An easy method of staining the gonococci was with methylene blue. A saturated solution of methylene blue in absolute alcohol should be kept as a stock solution. A few drops of this added to an ounce of water would be sufficient for making many stains. In a few cases coming very early under observation he had found no gonococci, and had, therefore, been led to make a diagnosis of a non-specific urethritis. A few days later the microscope had shown a pure culture of gonococci. A single injection of protargol would often cause a disappearance of the gonococci for twenty-four hours. Acute gonorrhœa was a self-limited disease, but by improper treatment or lack of constitutional vigor the disease was apt to last for an indefinite period. Some patients would recover under inefficient treatment, or even under no treatment; but, as a general rule, the earlier the diagnosis of gonorrhœa could be made, and efficient treatment instituted, the sooner would a satisfactory cure be effected. There was a vast difference between a first attack and the subsequent ones, in their reaction to treatment. Hot irrigations had been found to be soothing to the urethral canal, and he made use of a 1:4,000 solution of permanganate of potassium. The temperature should be between 105° and 110° F., and gradually increased to 120°. The test of the irrigation was its effect on the patient; it should be non-irritating. Protargol should be used in the strength of one-half to two per cent., the strength being graded according to the effect on the patient. It should not be irritating, and it was often useful for the first few days to employ a mixture of protargol and cocaine solution. For the first three or four days the injections should be given twice a day; then the treatment should be given once a day for a week, and after this at increasing intervals, until by the fourth or fifth week there was only one treatment a week. The patient was then instructed to drink beer freely for several days, to determine whether it would set up a fresh urethral discharge. Dr. Swinburne personally preferred to begin local treatment at once, no matter what the stage of the disease. The utmost gentleness of manipulation and great patience were requisite in the successful treatment of gonorrhœa. As soon as the posterior urethra had become invaded it was his practice to treat that part locally, giving a daily treatment. When the catheter could be used without discomfort to the patient it was useful, but when it caused irritation its introduction often caused more harm than did the disease. Instead of forcing the fluid past the compressor muscle, the patient should be instructed how to relax this muscle at the right moment. Some cases of posterior urethritis could be best treated by the deep instillation of protargol solution.

Chronic Gonorrhœa.—Dr. John Van der Poel discussed this subject. The treatment, he said, was practically that of the acute disease, except that greater liberty could be permitted in diet and exercise. In anæmic and poorly nourished individuals general tonics and alcoholic stimulants, with proper exercise in the open air, would often be more beneficial

than local applications. Alkalies and diluents for the scalding urination were indicated, and later the oleoresins. One should avoid unnecessary instrumentation, and should secure sufficient rest between the treatments. The local procedures should be directed against the gonococci or other micro-organisms that might be present, and also against the results of the attack of these organisms. The best remedy for the destruction of gonococci was protargol. The ordinary urethral syringe was not sufficient for a thorough washing. Much to be preferred was the system of irrigations with a fountain syringe. If the posterior urethra was involved, the irrigation must reach the bladder, and to overcome the spasm of the compressor muscle it was well to use a solution of cocaine. When there was much scalding, it was well to avoid instrumentation. For anterior urethritis the protargol should have a strength of 0.5 to 1.5 per cent., and the quantity should be 500 to 1,000 gm.; for posterior urethritis the strength should be one-half to one per cent., and the quantity 200 to 500 gm. This treatment should be given daily. The strength of the solution should be gradually diminished, and the interval lengthened. When secondary infection was present, he employed dilute solutions of bichloride of mercury. When all micro-organisms had disappeared, weak astringent solutions of acetate of zinc, acetate of lead, or sulphate of zinc were beneficial. When there were patches of inflammation in the urethra, the application of nitrate of silver in the strength of one-half to five per cent., or of sulphate of copper of the same strength, was to be recommended. From two to ten minims should be used, one, two, or three times a week. The sphere of the endoscope was limited, but not so limited as many would have us believe. Generally speaking, this instrument should not be used until other methods had failed, or there were special indications for its use. At times, instrumental dilatation and injections should be combined, either special dilators or the ordinary urethral sounds being used. The best astringents were bichloride of mercury, silver, and Ultzmann's solution. A sudden increase of discharge containing gonococci probably indicated that a new focus had been broken open. In general, the dilating sounds should not be used while micro-organisms were present. Chronic inflammation of the posterior urethra rarely remained superficial. Involvement of the prostate was of very frequent occurrence. Here prostatic massage and irrigations should be employed.

Complications of Posterior Urethritis.—Dr. J. Pedersen discussed this topic. He said that the underlying principle of treatment was to avoid whatever would directly or indirectly cause hyperæmia of the genital apparatus. By this it was meant that one should endeavor to secure recumbency, an antiseptic state of the urine, the use of a milk diet, abstinence from alcohol, tobacco, and coffee, and avoidance of instrumentation or irrigation. In the treatment of urethrocystitis the urine should be made as bland as possible, and this implied the use of a milk diet, the free ingestion of water, and the internal administration of urinary antiseptics. The best of the last was salol, given in full doses. Hyoscyamus or morphine might be required. A fair proportion of the patients did well without any local treatment, while others would be improved by hot irrigations with a double-current irrigator. In the more severe cases a catheter should be very gently introduced, and a drachm or two of a solution of nitrate of silver, of the strength of one-half to one grain to the ounce, should be instilled. This usually gave great relief, but if it did not, a one-per-cent. solution of protargol should be substituted. Irrigation of the bladder from the meatus, with a warm solution of boric acid or other mild antiseptic, could sometimes be performed without causing much discomfort; but ordinarily this procedure was painful and irritating, and should then be avoided. Irrigation of the bladder from the meatus, it should be remembered, was dangerous under these conditions, because of the danger of driving some of the fluid into the ureters, thereby exposing them to infection either by contact or by the induced hyperæmia. Acute general cystitis was an infrequent complication of posterior urethritis. If possible, instillations should not be employed in the early stages. Forcible irrigation of the bladder should be condemned. The treatment of ureteropyelitis consisted in the application of fomentations, cupping, diaphoresis, and catharsis. Resolution was the rule in recent cases. Gonorrhœal inflammation of the spermatic cord was also a common complication. The treatment usually consisted in suspension of all direct treatment of the urethra, recumbency, the application of an ice bag or of an evaporating lotion, and the administration of a mercurial purge. In the subacute and chronic cases, whether or not suppuration had occurred, moist heat would favor resolution. If the patient would at once go to bed as soon as there was aching in the groin, and would have an ice bag applied to the part, he might be spared an epididymitis. In the first twenty-four hours an ice bag was indicated, but if the case was not seen until later, or if the ice bag failed to give relief, warm applications should be substituted. In the later stages, mercury and iodide of potassium should be employed. Suppuration was not common. The ordinary suspensory bandage was not sufficient for these cases; the scrotum should be reflected up over the pubis, and by means of a sling attached to a band around the waist the testicles should be given thorough support. In acute prostatitis, relief would often be afforded by frequent irrigations with hot decinormal saline solution. The indications for the treatment for acute seminal vesiculitis were the same as for acute prostatitis, with the addition of measures to relieve the annoying and persistent priapism. Gonorrhœal rheumatism might occur at any time in the course of an anterior or posterior urethritis. Internal medication was directed chiefly against the constitutional disturbance. Oil of gaultheria would seem to be the most reliable of the antirheumatics. The local treatment was important. Immobilization by splints, counterirritation, and cold were indicated in the early stages; later, poultices and compression were in order if effusion had occurred. Still later, massage and passive motion should be employed. In the severest cases of suppuration, arthrotomy, irrigation, and drainage might become necessary. The treatment of the urethritis should be active, though conservative. Instrumentation in acute urethritis seemed often to precipitate an attack of gonorrhœal rheumatism in a predisposed individual.

Gonorrhœal Conjunctivitis.—Dr. W. A. Holden read this paper. He said that in from one to four days after infection the first signs manifested themselves—swelling of the eyelids and a watery discharge. A day or two later a thick, creamy, purulent discharge filled the conjunctival sac and poured out of the aperture of the lid. In this early stage the conjunctiva sometimes sloughed very rapidly. When a patient with suspected gonorrhœal conjunctivitis was first seen, the discharge should be examined microscopically, thus perhaps saving much needless anxiety. At the very beginning a single application of a two-per-cent. solution of nitrate of silver or of a fifty-per-cent. solution of protargol might cut short the attack. The most essential portion of the treatment was the almost constant use of ice cloths and the very frequent washing out of the eye with a saturated solution of boric acid. The cornea should be inspected at least once a day, and at the very first sign of haziness the cold applica-

tions should be decreased or hot applications substituted. Protargol might be employed from the beginning of the disease, being applied to the everted lids. When ulcers of the cornea developed, they should be touched with tincture of iodine, carbolic acid, or the actual cautery. Such cases were most successfully treated in hospitals.

Gonorrhœal Stricture of the Urethra.—Dr. J. R. Hayden took up this topic. He said that the best routine treatment for recent or fairly recent cases of gonorrhœal stricture was gradual dilatation with proper irrigations. If such treatment, after having been given a faithful trial, should fail, then cutting operations would be demanded. Stricture of the meatus, or near this point, did not generally yield to dilatation, and must, therefore, be cut under cocaine anæsthesia. The incision should be made downward in the median line, and the urethra should then be irrigated and dilated. If a stricture in the pendulous urethra was soft and yielding, it should be treated with soft bougies at intervals of a few days, until a No. 18 bougie could be introduced, when steel sounds should be employed. If such treatment failed, internal urethrotomy should be done. The important point to remember was that the cutting instrument should be held firmly in the median line and the urethra kept on the stretch during the division of the stricture. The stricture should be cut until a calibre of No. 25 or 30 had been secured. If after the operation there were any signs of urethral fever, all of the urine should be drawn with sterilized catheters and the urethra washed out with a warm antiseptic solution, while urinary antiseptics should be given internally. For obstinate and tough strictures of the deep urethra, external urethrotomy should be done. The patient should be prepared for the operation by a few days' rest in bed on a light and non-stimulating diet. If possible, a tunnelled sound or a filiform bougie should be introduced as a guide, and the incision into the urethra made upon this guide from without. All strictured tissue should be excised, and a full-sized sound introduced into the bladder at the close of the operation. A perineal drainage tube should be inserted. This was ordinarily removed permanently on the fourth or fifth day. Usually at the end of a week most of the urine would pass through the meatus. A sound should be introduced every second or third day, and a sound should be passed on such a person at intervals of from six to twelve months for the rest of his life. If the stricture would admit of the passage of a filiform bougie, it might be used as a guide for the passage of a number of instruments. This was known as rapid dilatation—a method which was never free from risk. Continuous dilatation was occasionally useful in selected cases. Electrolysis was useful in only a few soft, dilatable strictures, and was mentioned here only to be condemned.

Dr. Robert W. Taylor said he thought the tendency of to-day in medicine was to forget many useful things well known to our forefathers. He was not one of those who was impressed with the necessity for aborting or jugulating gonorrhœa. The treatment of gonorrhœa should not be too active in the first stage. Genito-urinary surgeons had passed through a very heated term some years ago concerning the bichloride-of-mercury treatment, and very few of the former advocates of that treatment would be willing at the present day to stand by the statements they then made. The early use of copious injections of permanganate of potassium did harm by their mechanical action. In the speaker's opinion, it was much better in the first week to soak the penis frequently in hot boric-acid solution. The diet and bowels should be regulated and alkalies prescribed. As soon as the inflammatory symptoms had subsided, it was well to use warm lead water, and to remember that, no matter how little we knew of the rationale of their action, antiblennorrhagics were useful when substituted for the alkalies. He was inclined to hold that strong solutions of protargol would not be used so much if nitrate of silver was employed in an efficient manner. He had no fondness for these bastard and emasculated preparations of silver. He would begin with a solution of nitrate of silver 1:32,000, and using one or two ounces, would irrigate the urethra once or twice a day. If the patient suffered no special discomfort, and the discharge diminished, one might be sure that the treatment was well adapted to the case. The strength of the solution should be gradually increased until at the end of five or six weeks instillations of 1:500 solution of nitrate of silver might be used. Long-standing cases required solutions of acetate of lead, sulphate of zinc, or sulphate of copper. Here these were invaluable, but in general the rules laid down, he knew from a long experience, would prove most satisfactory.

Dr. B. Lapowski said that protargol could never reach the gonococci situated deeply in the tissues. The different results of treatment of gonorrhœa in the urethra and gonorrhœal inflammations of the conjunctiva were dwelt upon, and this was attributed to the greater ease with which the gonococci could be reached in the conjunctiva. The aim of the physician should be to locate the deeply lying foci of gonococci in the urethra. The speaker laid stress upon the point that the microscope did not always demonstrate the presence of gonococci. Certain of these organisms, he said, did not take the Gram stain, and they appeared under the microscope as involution forms. To determine absolutely whether or not a gonorrhœa had been cured, and that it was permissible for the individual to marry, culture tests must be made.

Dr. Ramon Guiteras said that not infrequently fresh infections of gonorrhœa arose from hidden foci, usually in the posterior urethra, though sometimes in the anterior urethra. This explained some cases in which the patient was positive that there had been no exposure to new infection, and was sure that this trouble was due to a "strain." Some years ago he had seen many cases cured, or apparently cured, by copaiba and sandal-wood oil. Zinc, lead, opium, and other astringents would always find a useful place in the treatment of gonorrhœa. Of the lately introduced so-called specifics, he looked upon protargol as by far the best. It was the best remedy for introduction in solution into the urethra. As a rule, all solutions containing silver salts were much better than other solutions. With permanganate-of-potassium injections he believed gonorrhœa could be more effectively treated than by any other means. The hydrostatic pressure should be carefully and intelligently regulated, and if this was done, it would be possible after two or three trials to irrigate the bladder as well as the urethra without undue shock to the compressor muscle. Since these permanganate injections had come into vogue, urethral strictures had been very much fewer, yet seminal vesiculitis was certainly more common.

Dr. Charles Chetwood asserted that there was no routine treatment equally suitable to all cases of gonorrhœa. The two treatments directed against the microbic factor of the disease embraced (1) an abstinence from all local measures for several weeks, with the object of allowing the micro-organisms to become attenuated, and (2) the antiseptic method. He had become a convert to the latter because he had learned that, when properly employed, it decidedly curtailed the duration of the disease, and rendered it less likely to be followed by complications than was any other method in vogue. The purpose was not to destroy the gonococci after one or two applications, but to destroy the free gonococci in the urethra and render the urethra a poor

culture medium for the micro-organisms. Clinical experience had proved that it did really accomplish this. He objected strongly to forced irrigation without a catheter in acute urethritis. The treatment should be confined entirely to the anterior urethra in the first five or six days of the disease. At the end of the first week, even though the disease had not reached the posterior urethra, it would be so close to this part that treatment of the posterior urethra would be justifiable as a prophylactic measure.

Prophylaxis of Gonorrhœa.—Dr. Bischoff spoke of the prophylactic treatment of gonorrhœa. The chief source of infection, he said, was the prostitute, and, although prostitution was difficult to control completely, one should not hesitate to do what was practicable in this important field. From a study of the measures employed in Berlin, he had been led to think that the failure there was because it was entirely a police measure, and also because medical supervision and treatment did not go hand-in-hand. He thought a good deal more could be accomplished here by placing this matter in the hands of our sanitary authorities. The subject of personal prophylaxis of gonorrhœa had received attention only in recent years, and that abroad. Frank, in a series of experiments covering six cases, had been able to prove that it was possible to abort gonorrhœal infection. This he had done by inoculating six males with gonorrhœal pus, and using immediately afterward in three of them an injection consisting of a twenty-per-cent. glycerin solution of protargol. These three did not develop gonorrhœa, while the other three who had not been so treated, in order to serve as a control test, had developed the disease. The speaker said that he had employed a quick cure devised by Frank. It consisted in flushing the urethra with certain solutions. Frank had reported that in sixty cases a cure had been effected in three days. The treatment was still experimental, and could be employed only in selected cases.

Use of Picric Acid.—Dr. Hill said that nothing had been said about the use of picric acid in chronic gonorrhœa. He had used it in a considerable number of cases during the last year, and had found that when the mucoid stage was present, and it was very difficult to clear it up—in other words, when the posterior urethra was involved and there was a peculiar fibre floating in the urine, and floating readily in this fluid—picric acid should be used in the strength of 1 : 1,000 or 1 : 2,000. About ♏ lx. should be used for each instillation.

Dr. Ferd. C. Valentine expressed the opinion that there were various forms of the gonococcus, and the reason why certain preparations acted so brilliantly in particular cases was because each of these preparations was a specially potent destroyer of a particular form of the gonococcus. He objected to the use of cocaine preliminarily to either instrumentation or injections into the urethra. It might relieve pain temporarily, but most persons in whom it was employed experienced more prolonged pain afterward than those in whom cocaine was not used. Far better than the use of such anæsthetics was the uniform employment of extreme gentleness in all manipulations in the urethra.

SECTION ON SURGERY.

Stated Meeting, March 11, 1901.

John B. Walker, M.D., Chairman.

Acute Appendicitis in the Presence of Tuberculous Peritonitis.—Dr. Howard Collins presented this case. The patient was a man who had come under observation in hospital, about the middle of February. On making an incision at the outer edge of the rectus muscle and opening the abdomen, the speaker had been struck with the absence of fluid. Closer inspection had shown the coils of intestine to be covered with miliary tubercles. The appendix contained five fecal concretions but no tubercles. The patient had made a good recovery from the operation on the appendix, and his general condition had improved, though there was a slight daily febrile movement.

Tuberculosis of the Vas Deferens and Seminal Vesicle.—Dr. Victor C. Pedersen presented a man forty-seven years of age, who had been admitted to the hospital on December 7, 1899, and had been operated upon by Dr. Weir. Three weeks before admission an abscess had formed, and had broken into the scrotum. Examination had shown the testicle and epididymis to be enlarged and nodular. The sinus left by the abscess admitted a small probe. The vas deferens was nodular in the scrotum, canal, and pelvis. The urine did not contain tubercle bacilli. On December 12, 1899, Dr. Weir had done a castration and an ablation of the diseased area. The diseased testicle and the stump of the vas deferens had been enucleated. Certain sinuses had been left after the operation, and when the patient had been next seen, on June, 1900, these were still leaking a little urine and fæces. The urine was still cloudy and clear by turns, the three-glass test showing quite turbid urine and shreds in the first, a little less turbidity in the second, while the urine in the third glass was almost invariably perfectly clear.

A Case of Double Penis Combined with Exstrophy of the Bladder.—Dr. Carl Beck presented a small infant suffering with this rare condition. He said that only a very few similar cases had been reported.

Fissure of the Upper End of the Humerus.—Dr. Beck also presented this case, occurring in an elderly woman, who had fallen about five weeks ago, striking the right elbow on the pavement. There had been ecchymosis at the elbow at the time, suggesting a fracture there, but no fracture had been found at this point. When examined by Dr. Beck, four days later, there had been absolutely no objective symptoms of fracture, except a slightly abnormal mobility in the region of the head of the humerus. The pain here was intense. There was, however, no swelling or deformity. A skiagraph of the case was presented, showing a fissure line running downward and inward from the tubercles to about the surgical neck of the humerus. A skiagraph taken two weeks later, and viewing the bone from the back, showed a line which might lead one to look upon the case as one of fracture of the anatomical neck. The second skiagraph showed also chips of bone—a condition which he had not infrequently met with in other cases supposed to be only examples of contusion. When such chips of bone could be made out, the massage treatment for sprains would be manifestly inappropriate.

Osseous Cyst of the Tibia.—Dr. Beck also presented a case of osseous cyst of the tibia. He said that such cysts unfortunately resembled very closely osteosarcoma, though they were themselves benign growths. The proper treatment was incision and evacuation of the cyst, not amputation as in the case of osteosarcoma. The history of the two conditions was also not dissimilar. The diagnosis was sometimes made by an exploratory incision, but his own studies had led him to believe that it would be possible, after a more extensive experience, to make the diagnosis by the aid of the *x*-rays. The cortex of an osseous cyst would be found distended, but not irregular, as in the case of an osteosarcoma. The case presented was that of a young boy, who seven months ago had fallen into a street excavation. In two days he had been able to walk around. Shortly afterward he

had fallen again, and had then been confined in bed for some time. A few months after this, he had fallen for the third time, and had been confined to bed for six weeks. A surgeon had seen the boy at this time, and had told the mother that there was a malignant growth present. Certainly that was the appearance of the case, but after an examination with the *x*-rays Dr. Beck said he had felt justified in advising an exploratory operation. On incision, viscid bloody serum had been evacuated, and after curettage the bony walls had been so thin that they could be easily brought together by pressure with the hands, thus obliterating the cavity. Healing was now nearly complete.

Dr. John F. Erdmann said that from his examination of the case of exstrophy of the bladder he had been led to suspect the presence of a third ureteral orifice, and he would like to hear a subsequent report on this point.

Indications for Ligation of the Jugular Vein in Sinus Thrombosis.—Dr. Fred Whiting read this paper, and presented illustrative cases. The author divided sinus thrombosis into three stages, viz., a first stage in which there was a parietal thrombosis, partial or complete; a second stage in which the thrombosis had undergone disintegration, with septic absorption; and a third or still more advanced stage of pyæmia. The second stage was essentially a condition of septicopyæmia. The very high temperature indicated the degree of pyæmia present. The nearly vertical lines of elevation and remission on the temperature chart in the stage of septicopyæmia constituted a most characteristic picture. These rapid fluctuations in temperature, associated with rigors and followed by colliquative sweats, were characteristic of the second stage. Sometimes the sweating continued almost uninterruptedly during the second stage, and this incessant drain rapidly weakened the individual. Neither the pulse nor the respirations presented anything especially characteristic. Vertigo and vomiting were present in a moderate proportion of cases which were uncomplicated, but were much more common in cases complicated with meningitis. They were present at times only when the patient was in the erect posture, while at other times they were observed while he was in the recumbent position. Consciousness might be lost very early, or it might be retained up to death. A mild form of delirium did not necessarily imply greatly increased gravity, but if prolonged and increasing in severity, the prognosis was bad. Septic pneumonia and enteritis, with albuminuria and affections of the pericardium and pleura, were occasionally encountered, and usually indicated a rapidly approaching fatal termination. Engorgement of the veins tributary to the dura mater, and tenderness in the upper portion of the posterior cervical triangle, he had found uniformly present, and looked upon them as important signs. They usually meant that thrombosis had already extended into the upper part of the jugular. The so-called Griesinger symptom consisted in an œdema of the occipital region, extending downward and implicating the nape of the neck. It should not be confounded with the ordinary œdema of the mastoid region, occurring in uncomplicated cases of mastoiditis. When the finger was laid across the external jugular with sufficient pressure to obstruct the flow of blood in the vein, it would be noticed that the jugular on the affected side would not show the prominence that it did on the well side. This sign was best elicited by pressure made just above the clavicle. Tenderness along the course of the internal jugular vein in the neck was a symptom developing late in the second stage, or at the beginning of the third stage. When peripheral thromboses were present, the diagnosis became distressingly clear, and correspondingly hopeless, unless prompt resection of the jugular was done. The speaker said he believed that ligation of the internal jugular should be practised much more frequently than had usually been done by general surgeons and even by otologists. He asserted that it was the duty of the operator to qualify himself for such work, and not to hesitate to do these extensive and radical operations in most cases of the class under consideration. Intravenous infusion had greatly diminished the danger of shock, and his own experience had led him to believe that the infusion of a very hot saline solution (135° F.) was especially useful as a means of stimulating a flagging heart. His own opinion was that ligation of the jugular should be practised whenever a clot in the sinus had invaded the bulb, irrespective of recognizable purulent disintegration. When a clot formed farther back, it was easy to assure one's self that all septic products had been eliminated, but this was not the case when the bulb had been invaded. Ligation of the jugular was indicated also in the presence of a clot, irrespective of its situation, if pronounced symptoms of septicopyæmia were already present. It should, of course, be performed when the thrombus had undergone purulent disintegration, even though the bulb were apparently free from involvement. Ligation of the jugular was also indicated when the thrombus was situated far back toward the torcular, and there were visible respiratory movements of the parietal thrombus wall. The presence of embolic metastases, and the appearance of circumscribed infiltration along the course of the internal jugular, were pathognomonic signs of pyæmic sinus thrombosis, and jugular ligation should be at once performed as a judicious prophylactic measure.

Dr. Percy R. Bolton said that it had always seemed to him that if the internal jugular was to be tied at all, it should be done as the first step of the operation, and that the vein should be resected as well as ligated.

Dr. J. A. Blake took the same ground regarding the advisability of breaking the continuity of the jugular vein, and doing this at the beginning of the operation. He thought there must be great danger of detaching infected particles during the operation, and if the vein had not been already ligated this should lead to metastases. He understood that there had been a nigher percentage of recoveries from operations in which the vein had been ligated.

Dr. Francis J. Quinlan was of the opinion that in cases of acute mastoiditis, the inspection should embrace the antrum and cells.

Dr. Whiting said that, in the use of the term jugular ligation, he assumed that every one would understand that at the present day this included jugular resection. He thought that the symptoms of sinus thrombosis would have to be clear and unequivocal to justify resection of the jugular as a preliminary to operating upon the skull. If this rule were not followed, one might have the unfortunate experience of obliterating and removing the jugular, only to find on entering the skull that there was no sinus thrombosis there.

Benefit of Operation.—The president related the case of a patient with some obscure form of abdominal disease. The abdomen was opened, and on examination it was found that the whole of the visceral and parietal peritoneum was studded with little masses like grains of sago. The patient made a rapid recovery from the laparotomy, and got completely well. The explanation given by the pathologists was that the tubercle bacilli being anaerobic, the exposure of the peritoneum to light and air had the effect of destroying the organisms.—Royal Academy of Medicine of Ireland.

Therapeutic Hints.

Chloroform has been found a valuable vermicide in doses of four grams—thirteen cases.—LEICHTENSTEIN.

Diuretic and Anti-Uricæmic Pills.

℞ Ext. stigmat maidis,
Ext. convallariæ maialis,
Sodii benzoat,
Lithii carbonat.....āā 3 gm.
M. ft. pil. No. lx. S. Give from four to ten daily.
—HUCHARD.

Bronchitis (subacute).—

℞ Strych. sulphat..... gr. ss.
Codeinæ..... gr. ij.
Terpin. hydrat..... gr. xxiv.
Guaiacol carbon..... gr. xl.
M. ft. caps. No. xii. S. One every three hours.
—*Clinical Excerpts.*

Agoraphobia is best cured by hypnotic suggestion. Two instances in which there were nervous symptoms when the patients entered churches, theatres, shops, etc., with depression, anxiety, etc., are reported cured. —TUCKEY.

Chloralamid may be given as a hypnotic in insomnia of neurasthenia or of mild insanity, in the following combination:

℞ Chloralamid..... ʒ ij.
Spts. frumenti,
Syrupi rubæ idæi.....āā ʒ i.
M. S. One-half teaspoonful at a dose. Two or three times this sized dose can be given if necessary.
—CLEVENGER.

Wax in the Ear.—Instead of the slower procedures with oil, glycerin, and soapsuds, use for about five minutes before syringing a half-strength peroxide-of-hydrogen solution.

Eczema.—

℞ Pulv. calaminæ..... ʒ i.
Ung. zinci.....ad ʒ i.
—STELLWAGON.

When much itching is present:

℞ Vini opii..... ʒ i.
Liq. plumbi subacet..... ♏ xxxvi.
Aquæ rosæ.....ad ʒ viij.
M. S. Apply.
—SMITH.

Follicular Pharyngitis.—

℞ Iodi,
Potass. iodidi.....āā gr. iij.
Acid. trichloracetic..... ♏ vij.
Glycerini,
Aquæ.....āā ʒ iv.
M. S. Apply locally, varying the strength according to conditions present.

Creosote Wine.—

℞ Creosot..... ʒ ss.
Tinct. gentian..... ʒ i.
Spir. vini rect..... ʒ viij.
Vini xerici.....q.s ad O ij.
To be used several times a day unless much fever be present.
—*Nouveaux Remèdes.*

Pruritus Ani.—

℞ Sodii hyposulphit..... 30
Acidi carbolici..... 5
Glycerini..... 50
Aquæ..... 450
M. S. Apply frequently by means of wet compresses.
—*Practitioner.*

Phthisis.—It seems to me that there is an analogy between cases of tuberculous peritonitis cured by operation and exposure to air and light, and lung cases, and if it is agreed that these organisms are anaerobic, and are destroyed by the influence of pure air, we must recognize that the open-air treatment is a distinct and specific treatment. We must remember, as Sir J. W. Moore has pointed out, that in addition to open air there must be sunshine, and that the air must be pure and must be still.—SIR CHRISTOPHER J. NIXON.

Fetid Breath.—

℞ Thymol..... gr. viij.
Spir. vini rect..... ʒ i.
Glycerini..... ʒ ss.
Formol..... gtt. viij.
Aquæ.....q s. ad ʒ viij.
M. S. Use as mouth wash, especially when fetor is due to decaying teeth.

Orchitis.—

℞ Lanolin..... 40 parts.
Guaiacol..... 5 "
Methyl salicylate..... 20 "
M. S. Apply.

Hypnotism is highly recommended in chronic constipation in women, which is curiously very favorably influenced by suggestion.—FROEMNER, *Soc. Méd. de Hambourg.*

Primary Tuberculosis of Larynx.—

℞ Acid. phenic..... 1. gm.
Iodi..... 0.05–0.10 "
Potass. iodidi..... 0.10–0.25 "
Tinct. opii..... 1.–2. "
Glycerini..... 45.–120. "
M. S. Use a teaspoonful in a glass of tepid water morning and night.
—SENESSE.

Pernicious Anæmia.—

℞ Fowler's solution..... ʒ iss.
Acid phosphate..... ʒ iij.
Bone-marrow extract..... ʒ viij.
M. S. Dessertspoonful after each meal.

Malaria, Fever, Bronchopneumonia, Pertussis.—

℞ Quininæ hydrochloro-sulphat..... 2.50 gm.
Aq. destil..... 10. "
M. S. Inject 1 to 2 c.c.
—GRIMAUX.

Or—

℞ Quininæ sulphat. (neutral)..... 10 gm.
Aq. destil..... 120 "
M. S. Inject 5 to 10 c.c.
—MAURANGE.

Or—

℞ Quininæ sulphovinat..... 2.50 gm.
Aq. steril..... 10. "
M. S. Inject 1 to 2 c.c.
—HUCHARD.

Fetid Bronchitis and Pulmonary Gangrene.—

℞ Myrtol..... 10
Ol. olivæ steril..... 100
M. S. Inject hypodermically 10 c.c.
—MAURANGE.

Neurasthenia.—

℞ Sodii phosphat..... 1
Aq. laurocerasi..... 50
M. S. Inject 0.10 to 1 gm. daily.
—CROCQ.

Sialagogue and Sudorific.—

℞ Pilocarpin. hydrochl..... 0.05
Aq. sterilis..... 10.
M. S. 0.005 to 0.015 daily by injection.
—*Rev. de Thérapeutique*, Jan. 1, 1901.

Sclerosis *en plaques.*—Potassium iodide in moderate doses (Raymond). Nitrate of silver (Charcot). Arsenic subcutaneously (Erb). Chloride of gold in association with freshly prepared tincture of hyoscyamus; the first in dose of 5 cgm. three times a day, the second in 1 to 2 gm. doses at meal time (Hammond). For the trembling, strychnine and solanine, the latter in daily dose of 10 cgm. As external measures, "firing" along the vertebral column, hydrotherapy, and electricity.—PAUL SAINTON.

Surgical Suggestions.

Abscess Cavities are best treated by application of carbolic acid in full strength, together with after-drainage.—Seneca Powell.

In Slowly Healing Surfaces cover with the inner membrane of the shell of a freshly laid hen's egg, and over this place a sterile leaf of tin foil.—Amat.

Spinal Anæsthesia.—The chief danger of the method, in my opinion, is the danger of an imperfect asepsis; hence, I believe that it is a method to be used not by everybody, but only by competent, skilled, and careful surgeons. Nor do I believe it will ever replace chloroform or ether as a routine anæsthetic.—W. W. Keen.

Hemorrhage in Fibroid Tumors of the Uterus.—Thorough curetting of the cavity of the uterus is the most certain method of controlling the hemorrhage. By this procedure the diseased endometrium is removed, and the bleeding is usually very decidedly diminished for several months afterward.—Charles B. Penrose.

Three Cardinal Signs of Appendicitis.—1. Sudden acute pain in one previously well. 2. Unnatural rigidity of the abdominal wall. 3. Hardness over the site of the appendix at McBurney's point.—Deaver.

Appendicitis.—Tenderness is increased in 1, early pus formation; 2, gangrenous change; 3, perforation. Tenderness is decreased in 1, discharge of fecal concretion; 2, after free evacuation; 3, in late pus cases with enough septic absorption to paralyze nerve filaments.—Charles B. Parker.

Preparing for Operation.—The patient having undergone a preliminary course of treatment for a few days by the administration of medicine, careful dietary, and the use of cleansing baths, on the morning of operation, or the previous evening, has the surface of the part to be operated upon, and surrounding parts, carefully prepared by washing and shaving, then washing with an alcoholic and ethereal solution of sterilized green soap and hot water. All the soap is washed away with the sterilized hot water; the skin is then dried with a sterilized towel, after which it is wiped over with ether to remove any grease remaining. It is then sponged over with an alcoholic solution of mercury biniodide 1:500, which may be allowed to dry by spontaneous evaporation; a dressing of sterilized dry wool or gauze is then applied, which is covered with waterproof material and bandaged on. This dressing is not removed until the moment before the operation commences, when the skin may again be moistened with the alcoholic solution of biniodide.—C. Y. Pearson.

To Shorten the Round Ligament.—Make an incision nearly three inches in length, open the inguinal canal from, and including, the external ring to the internal ring, lift up and isolate the round ligament, dilate the internal ring, incise the peritoneum and enter the peritoneal cavity through this opening for the purpose of breaking up adhesions or removing diseased appendages. The redundancy of the ligament is then cut away, the peritoneum closed, and several layers of buried sutures are used to close the various structures and fasten the stump of the ligament. The operation is likened to Bassini's operation for hernia.—A. Goldspohn.

It is only in rare instances that the shortening of the ligaments is the operation alone indicated. My records show that in the thirty cases in which I have performed the operation the following supplementary operations have also been made: Curettage, twenty-three; perineorrhaphy, eleven; trachelorrhaphy, nine; posterior colporrhaphy, one; excision of hemorrhoids, three; excision of urethral caruncle, one; abdominal section for appendicitis, one, and for adhesion, one. Twenty-five were free from adhesions or disease of the tubes or ovaries. Ovarian prolapse was present in several of these. My own operation consists, briefly, of the following steps: An incision an inch in length to the depth of skin and fat only, situated about midway between the spine of the pubis and the anterior superior spinous process of the ilium, and parallel with, and just above, Poupart's ligament; separation of the cellular tissue overlying the tendon of the external oblique muscle by blunt hooks and retracting it, with the other tissues, with eye retractors; puncturing the aponeurosis with the scalpel just above Poupart's ligament; introduction through this quarter of an inch incision, of the blunt hook, and the withdrawal of the ligament; severing the fibrous attachments of the ligament to the tissue within the inguinal canal, and drawing the ligament through the internal ring; piercing the aponeurosis in two places and drawing the loop of ligament through them, and after folding this back on itself, making it fast by one buried suture; closing of the wound by superficial, fine catgut sutures and sealing with iodoform collodion, re-enforced with gauze.—Howard W. Longyear, *The Physician and Surgeon*, January.

Retroplacental Hemorrhage is most severe after the placenta is "squeezed off." If left to come off of itself there is very little bleeding as a rule.—A. V. Macan, president obstetric section, Royal Academy of Ireland.

Metacarpal Fracture.—Various experiments have proved that the metacarpal fragments are invariably held in place by elastic pressure. For this purpose two rubber drainage tubes of moderate size are chosen, which are lightly pressed into the adjoining interosseous spaces, so that they fill them to a certain extent. They are kept *in situ* by adhesive plaster strips passed around the hand. Thus, the recurrence of the displacement is prevented. The whole is surrounded then by a moss splint, a material which, after being dipped in cold water, adapts itself to the contours of the hand like a plaster-of-Paris splint, over which it possesses the great advantages of being absorbent and much lighter. The Roentgen rays should be consulted before one is satisfied as to the question of impeccable union.—Carl Beck.

Tuberculous Peritonitis.—The efficacy of simple incision is well shown in a case recorded by Abbé, of a woman who, for marked tuberculous peritonitis, was operated on by simple incision, and made a complete recovery. Two and a half years after she was operated on for a small ventral hernia; during this process the abdomen was inspected, and no trace of tubercle was discovered. In the ascitic form, five methods of laparotomy have been adopted: 1. Simple incision, with free evacuation of the fluid and closure of abdominal wound. 2. Incision, with subsequent flushing of the abdominal cavity with sterile water, saline solution, or some mild antiseptic solution, and closure of the wound. 3. Incision, flushing, and thoroughly drying the abdominal cavity, closing the wound. 4. Incision and drainage. 5. Incision, drying the peritoneum, and treating it with some drug, as iodoform, camphorated naphthol, etc., closing the wound. Laparotomy, with or without manipulation, is of great benefit in a large percentage of cases.—Walles.

Medical Items.

As to Quackery.—It is a curious characteristic of human nature, or of a great deal of human nature, that people who would grudge paying a cent to a regular medical practitioner will cheerfully pay a great deal of money to an irregular medical practitioner. Go where you will and you will find the quack prosperous. His rooms are full of patients, and his patients are full of faith. Men and women will buy wondrous remedies from travelling mountebanks who do not disdain to sing a comic song on the wagon from which they peddle their nostrums. Natural bonesetters, and long-haired "Indian doctors," and botanic doctors ignorant of botany, and faith healers of many kinds, abound; and the trade of most of them is good. The world likes to be healthy, but it loves to be humbugged. If a thousandth part of the blind, unhesitating faith that cleaves so readily to incompetent, and often illiterate, practitioners of fantastic means of healing were bestowed upon religion, there would be no complaints that the churches are not filled. But often those who are full enough of doubts of the supernatural so far as it relates to their souls are quick to believe in an almost or altogether supernatural gift of quack salves to cure the body. Legislation can do but little if anything to interfere with the gains of the medical pretenders or of the professors of visionary and semi-religious medical "science." You cannot legislate away a state of mind; and the state of mind of thousands, perhaps millions of persons, is one of crass credulity in humbug. Their delusions and illusions can be removed only by experience and a wider knowledge. They take their own lives and the lives of their families in their hands when they neglect the methods and the agents of modern medicine and surgery and resort to the moonshine of Christian "science," or to any other crank system, or to any individual quack. But you cannot prevent people from killing themselves if they have the will; and you will only stimulate faith in quackery by giving it a chance to yell "Persecution!" A private arrangement between patient and "healer" will nullify any provision of law forbidding the "healer" to heal for a consideration. A gift can take the place of a fee; and "gratuitous" treatment can be acknowledged with a gratuity. The best way to deal with a delusion is to let it alone. Common sense must win in the end.—*New York Sun.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 23, 1901:

	Cases.	Deaths.
Tuberculosis	278	165
Typhoid fever	23	5
Scarlet fever	607	40
Measles	319	4
Diphtheria and croup	300	59
Smallpox	41	6
Varicella	57	0
Cerebro-spinal meningitis	0	4

Influenza in Infants.—John Zahorsky gives the clinical forms of influenza in infants as follows: 1. Acute angina. 2. Acute coryza. 3. Acute laryngitis. 4. Acute bronchitis. 5. Bronchiolitis. 6. Croupous or broncho-pneumonia. 7. Myocarditis. 8. Leptomeningitis. 9. Acute gastritis. He declares that one or more of these types may be present in the same case. Acute myocarditis is characterized by cyanosis and coldness of the extremities, sighing respiration, and very feeble pulse. The temperature is usually subnormal. Infections of the fauces and lungs give rise to the most fever. Infections of the nasal cavities, larynx, and bronchi are not accompanied by much febrile movement. No prophylactic measures, except complete isolation from the family and visitors, are effective. In the case of feeble infants isolation should be ordered. It should be remembered that the act of coughing throws out a fine spray of mucous particles, which contain the bacilli. A coughing person is particularly dangerous in the nursery. Medicines have little or no effect on the course of the disease. The coal-tar antipyretics nearly always prolong the disease, and do harm. Quinine seems to do most good. Salicylates, benzoates, creosote, and salol have little or no effect. A cool bath at the height of the fever often lowers the temperature permanently. Stimulants are usually necessary. The diet must be careful. Hygienic and symptomatic treatment is all that can be instituted. No drug specially affects the disease favorably. —*St. Louis Medical Review*, February 23, 1901.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 23, 1901:

		Cases.	Deaths.
Smallpox—United States and Insular.			
District of Columbia, Washington	March 2d to 16th	10	
Florida, Jacksonville	March 9th to 16th	4	
Illinois, Chicago	March 9th to 16th	8	
Indiana, Terre Haute	February 4th to 11th	2	
Kansas, Wichita	March 8th to 16th	15	
Kentucky, Lexington	March 8th to 16th	1	
Louisiana, New Orleans	March 8th to 16th	14	4
Maryland, Baltimore	March 8th to 16th	1	
Michigan, Bay City	March 8th to 16th	2	
Detroit	March 8th to 16th	4	
West Bay City	March 1st to 16th	1	
Minnesota, Minneapolis	March 2d to 16th	11	
Winona	March 8th to 16th	26	
Nebraska, Omaha	March 2d to 9th	5	
N Hampshire, Manchester	March 8th to 16th	3	
New York, Elmira	March 2d to 9th	1	
New York	March 8th to 16th	37	6
Ohio, Cleveland	March 8th to 16th	46	
Toledo	March 8th to 16th	3	
Pennsylvania, Erie	March 8th to 16th	1	
McKeesport	March 8th to 16th	3	
Pittsburg	March 8th to 16th	2	
Steelton	March 8th to 16th	5	
Tennessee, Memphis	March 8th to 16th	20	
Nashville	March 8th to 16th	14	
Utah, Salt Lake City	March 2d to 16th	97	
Porto Rico, Aguas Buenas	February 8th to March 5th	2	
Bayamon	February 8th to March 5th	2	
Caguas	February 8th to March 5th	2	
Ciales	February 8th to March 5th	2	
Morovis	February 8th to March 5th	2	
Ponce	February 8th to March 5th	98	1
Quebradillas	February 8th to March 5th	4	
Rio Piedras	February 8th to March 5th	1	
San Juan	February 8th to March 5th	7	
Philippines, Manila	January 29th to February 9th	11	
Smallpox—Foreign.			
Brazil, Pernambuco	January 17th to 31st	..	25
Rio de Janeiro	February 16th to 28th	..	36
Canada, Ontario, Bracebridge	March 2d	2	
Georgian Bay	March 2d	Prevalent.	
Orillia	March 2d	1	
Penetanguishine	March 2d	1

THE RELATION OF THE PUBLIC TO THE MEDICAL PROFESSION.[1]

BY D. B. ST. JOHN ROOSA, M.D.,

NEW YORK.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY OF MEDICINE: In a great New York daily journal there recently appeared a leading article which objected to a proposed gift by the State to one of our colleges for the purpose of establishing a school of electrical engineering. Incidentally, in the argument against what was styled "paternalism in education," allusion was made to "medicine, landscape painting, pharmacy, and horseshoeing," as subjects which could with equal justice be placed under the endowment of the State, in favorable localities. This co-arrangement of schools for horseshoeing, landscape painting, and medicine was probably the playful satire of a journalist, and perhaps does not convey the deliberate view of a great newspaper as to the propriety of classing horseshoeing and the practice of medicine together, but it is in keeping with what may be often heard from the laity, as to the value of medical education and the proper position of the medical profession. Although I am not to make any argument, at this time, for State endowment of medical education, I wish to present some reasons why the medical profession deserves a great deal from the individual and from the public at large, whatever may be true with reference to the State.

The physicians and surgeons who practise their science and art in a given place, will mar or make the physical fortunes of the community. The most superficial view shows that every provision ought to be made in order that the education should be of the very highest order. It is not a mere matter of a trade that may be left to its own guild. The national government allows no illusions in regard to the value of medical education for its soldiers and sailors. Christian scientists, osteopathists, and imperfectly educated people of no pathy, but with a gift of healing, have no opportunity for exploiting themselves as medical officers of these two departments of the government. Like the State of New York, the United States is not content with a diploma of doctor of medicine and surgery for its medical officers, but the government insists on a separate, independent examination for general and technical qualifications before it allows a man to practise medicine and surgery among the soldiers of the United States army or the sailors and marines of the United States navy. But very few of our State governments are equally particular; while with many educated people of the public at large, any one who claims to be a practitioner of medicine may be safely tried, as one would try a well-recommended tradesman or mechanic.

In England and America the State relies on private means for the maintenance of hospitals and medical colleges. The time has come when these private means must be lavishly used, if we are to secure the proper medical colleges, for their plants have become very expensive. It requires the investment of a great deal of money to make a good doctor. This money is not only to be used personally by the student himself, but the apparatus and building, containing in these latter days a hospital and laboratory, are in themselves so costly that the expenses of the individual and the college combine together to make the course leading to the degree of M.D. a very dear one. During his four years the pupil must, foregoing almost all other occupations, devote his days and nights to study. Even the vacation is often spent as a substitute for one of the house staff in a hospital, so that the student cannot, as in an academic college or in a law school, use some of his time in earning the money he must pay for his tuition and living. Truly a man who devotes himself to medicine, in our State at least, must give his whole soul to his work.

There was a time when a medical school required simply a building large enough to contain an anatomical room, a chemical laboratory, and a lecture room. If added to this there was a small dispensary, it was deemed to be complete. But now, without a hospital with beds sufficient to allow the young man to be taught how "to do things"—in other words, how to diagnosticate disease and to apply remedies—the college is utterly unable to do the work which the advanced state of medicine and surgery requires. Then the laboratory, to which often the diagnosis must be referred for verification, or indeed for initiation, is also an expensive part of the plant.

As to the expense of a medical education to the individual, in former days in this country, a young man was often taken from the district school or, at the highest, from the village academy to begin the study of medicine; and if he spent two winters—or eight months in all—in a great city and filled up three years in very desultory work under the direction of a medical practitioner, he was doing all that was expected of him. Of course there was a certain proportion of men who had received thorough training before they entered on the study of medicine, and who devoted the whole of the three years to study, but this was not necessarily so, nor was it the case in the majority of instances. Now a preliminary examination is as important as the final one. It can be passed only by a graduate of a high school or of a college. This is true of our own State and of a few other States of the Union. It is easy to calculate the increased personal expense from the preliminary course and the four years in the medical school. If we add to this the fact that a considerable proportion of these students, after graduation, enter a hospital and spend eighteen months to two years without remuneration (except their board and lodging for a part of the term), we may have some idea of the expense of the study of medicine. What was formerly required only of men who wished to enter the army or the navy as medical officers, is now required of every man who wishes to practise in the State of New York. Christian scientists and osteopathists desire to be excepted, but thus far they have not obtained permission to practise without the professional

[1] Read before the New York Academy of Medicine, April 4, 1901.

qualifications which are required of those who seriously take up the study of medicine.

But the anxieties of the individual are not over when he leaves the medical college or the hospital. The young teacher or the young lawyer may expect a salary during the first year after his qualification, but the medical graduate must, unless under exceptional circumstances—for example, as assistant of an established physician—work his way alone, and, as a rule, he will have reached the manly age of thirty before he begins to earn a moderate living. Rich men, for obvious reasons, do not often make practitioners of medicine of their sons, but the working class of the community, with great self-denial and care, educate those who are to be the future guardians of public and private health or they educate themselves.

The benefit of this thorough preparation of the medical student comes to the community at large. These young men, as soon as they go out into the great and smaller cities, begin to work without salaries in the dispensaries and hospitals; and the community receives from them a very large service in gratuitous treatment. As to the country doctor he attends all calls without reference to the fees he may or may not receive. The doctor must seek his reward in professional renown, which pretty certainly leads in middle life to a competence for his yearly expenses, but which, in the vast majority of instances, leaves very little for the surviving family when the working hand is gone. It should not be thought for an instant that this hospital and dispensary service does not benefit the community at large, both directly and indirectly. It directly saves the taxpayers many burdens that they would otherwise bear, in preserving the laborers of the community from the results of disease and accident so that they may promptly recover and continue their work. Then the well-to-do citizen and his family get a large service indirectly from this experience thus gained; for the best physicians and surgeons, it is almost needless to say—although it seems sometimes to be denied in some quarters—are the men of the largest experience. A two-years' hospital experience is as valuable to a young man as would be ten years in active private practice. A man who has seen a hundred cases of a certain form of disease or of a certain kind of injury, and assisted in their management in a dispensary, will be much better adapted to treat similar cases when he encounters them for the first time in a private family.

There may have been once an idea, entertained by some few people who had given very little attention to the subject, that patients are cruelly treated in in the large hospitals. This may be true of hospitals where medicine is not taught, but it cannot well be when a hospital is a medical school, and thus under the supervision of the students and doctors who are watching every step of the treatment. It might be conceived to be true of hospitals to which students and practitioners have not full access, or where attendants, from the lowest to the highest, are created by political appointment; but in the private hospital of our day, with its experienced physicians and surgeons, with its band of trained nurses and its students or practitioners following with eager eyes the details of the management of cases and the results of treatment, experimentation, in the popular sense, cruelty or bad management cannot often, if ever, obtain. The more complete is medical control, the less likely are abuses to occur. The medical profession in the management of its hospitals in the army and navy of this country has never been justly complained of as to its medical, humane, or financial supervision except in rare instances, and has evoked the highest praise at home and abroad. The safety of the patient is greatly enhanced by the publicity which is given to all teaching hospitals.

The obstacles that were once placed in the way of medical education were not confined to hospitals. It is a remarkable fact that the boards of aldermen in this city, and the legislature of the State, in times gone by have not appreciated the necessity of anatomical study with sufficient understanding. They have endeavored to prevent doctors of medicine from learning what the law requires them to know. Not longer ago than half a century, Massachusetts and New York —probably other States—put everything possible in the way, by legislation to prevent the dissection of dead bodies. It is very creditable to our profession that the zeal for professional information and the desire to mitigate the suffering of the human race have enabled us, under very little encouragement, to force upon the community legislation which is for its own benefit—so slow has the public been to learn that the good health of the public is of the greatest service to the individual, and that educated and experienced physicians and surgeons are the best men to promote it.

What has the medical profession already achieved to deserve the confidence of the public?

The record of the last century, as detailed in one of our great newspapers by Osler and Keen, is sufficient justification for my claim that the public and the State owe so much to medical science, that they ought to cherish and maintain the medical profession at the highest point of perfection.

The close of the eighteenth century gave a brilliant forecast of what might be expected from its successor. Edward Jenner, by his discovery of the preventive power of vaccination, minified to such a degree what until his time had been one of the greatest scourges of the world that it is now a disease whose spread is easily stopped. Much of the beauty of the fair faces that now adorn our planet would have no existence but for the prevention of the spread of smallpox by the medical profession, and it alone.

In the nineteenth century the catalogue of achievement is long. The advances that have been made in medical science have not been the work of great syndicates with tremendous financial backing, and all the paraphernalia and money of great corporations in the full glare of the world, but oftentimes of private individuals, unaided by public funds, public institutions, or private gifts—alone in the laboratory or the consulting-room, or the wards of the hospital, or over the patient in the cottage of the hamlet or the tenement house of the crowded city. These great deeds have been self-inspired by the physicians and surgeons who have wrought them out. Mighty problems they have been.

The century began with Laennec with his discovery of the importance of using the ear in diagnosticating diseases of the heart and lungs. A simple discovery, but how important in its results! Osler says that it laid the foundations of modern clinical medicine. Then came Pasteur with his Alpine investigations which overthrew the theory of spontaneous generation. From this as a starting-point, a discovery of only forty years ago—or at least it is only forty years since it was made known—springs all modern bacteriology, whose verification and expansion are still going on. Many of its conclusions are as yet unsettled, but we know that the knowledge of the distinct forms of disease and the triumphs of modern surgery are based upon it. Thus the causes of pneumonia, diphtheria, tetanus, conjunctivitis, typhoid fever, suppuration in general, have been made plainer. Our surgery has become a safe and exact science and art.

During this century the cholera has been confined to its home in the valley of the Ganges; the bubonic plague is kept from ravaging our population, even if it set foot on our shores; the cause of yellow fever is being thoroughly investigated, and probably a decade

will not pass before it is understood as well as that of typhoid fever; the whole subject of the combating of toxins in the body by antitoxins is undergoing practical investigation, and some authorities think in the treatment of diphtheria that we have made an immense advance by the serum therapy, although some observers do not as yet admit this. We understand perfectly how to guard against typhoid fever, although what we know is not as yet fully used. It is not the fault of the medical profession that health boards and municipal authorities do not see the importance of thorough investigation of the milk and the water supply. The expense of providing such investigation would be infinitely less than what the fatal consequences of this disease now cost the State.

Tuberculosis of the lungs, or consumption, is being studied and treated with an intelligence that was never known before. In this State, private sanatoriums have already been firmly established, which diminish very much the dangers of the disease, and public hospitals are in prospect. There are also treatments based on an exact knowledge of the origin and course of tuberculosis, which promise very much to lessen the mortality from this dread destroyer.

One of the recent advances of medical science has resulted from the investigation of the cause of malarial fever. The first step toward the light was the discovery of the small bodies proved to be the specific germ of the disease. Some time after this, it was found that the parasite is carried by certain varieties of the mosquito to the human race; and the course of treatment became plain. Crucial experiments in the marshes of Italy, verified in England, prove this. Whether the mosquito is the sole carrier of the germ remains to be demonstrated. It is impossible to overestimate the importance of this discovery when we recall the extent and malignity of what we still call malaria.

In spite of the careful watching of the symptoms and progress of disease unaffected by drugs, by here and there a practitioner in advance of his times, the middle of the century found the profession everywhere engaged in overactivity in the treatment of disease. The delusion of homœopathy finally led to a more careful study of scarlet fever and many other affections, until the *vis medicatrix naturæ* really was allowed to exert itself without restraint.

In spite of the attractions of coal-tar preparations and other new and refined remedies constantly held out to us by pharmacists, there is a more decided scepticism as to the value of drugs, and while they are relied upon more implicitly when proved to be antidotes to poisons, they are much less indiscriminately and more exactly given.

No outline of the progress that has been made in our science in this century would be complete without an understanding of the great advance in the general establishment of hospitals and nursing-methods in large and small towns. As to the latter, the president of this academy and his contemporaries have lived to see the nursing in great hospitals changed from the care of untrained servants, who were not always clean and often were intemperate, to the careful nursing of well-brought-up and scrupulously neat young women and young men, without whose work the surgeon or the physician would be very far from carrying out his ideals.

The method of teaching medicine, as has been intimated in the beginning of this address, has been in general greatly improved. The long lecture without clinical illustration gives place to demonstrations. Men are taught to do things in the anatomical room, in the dispensary, and at the bedside. It has become the training that the artist gets in his studio, the engineer in the machine shop, the chemist in the laboratory, and the primary student of any well-taught science, and not entirely by what they are told or what they read, but also by what their own hands do and assist in doing.

One of the greatest discoveries of the nineteenth century is that of the production of general anæsthesia. The credit for this, as we all know, belongs to a Boston medical student who was practising dentistry for the purpose of enabling himself to carry on his studies and experiments—an example of what I have alluded to, that many of the investigations which led to medical progress were often made by private individuals, without the association of even their own medical colleagues. The ability to perform surgical operations was infinitely increased by the ability to perform them without pain, and when the practice of general anæsthesia by ether, and afterward also by chloroform, was well established in the profession, in due course from the wards of the Edinburgh Infirmary came the discovery of the chief origin of the infection of wounds. Indeed, this discovery was that it was an infection and not an inflammation.

Many years later came local anæsthetics, chief of which and first of which is cocaine, whose properties were discovered and promulgated by Dr. Koller, of this city, then a hospital physician in Vienna. This discovery is only a little inferior in importance in its application in one department of our surgery to that of general anæsthesia.

Within the last decade, the suggestions and experiments of one of our fellows, Corning, have enlarged the field of usefulness of cocaine as an anæsthetic, in providing a new method of producing general anæsthesia by injections into the membranes of the spinal cord.

Before this audience it is not for me to dwell on the importance of antisepsis in surgery. Lord Lister has lived to see the results of his own work, and so Morton saw thousands of painless operations before his untimely death occurred.

In the relatively small department of diseases of the ear, in the present century there has been a great development. Acute aural disease is thoroughly understood and efficiently treated, while the consequences of neglected disease are also thoroughly comprehended; and following in the footsteps of the great Irish pioneer, Sir William Wilde, modern investigators have made aural surgery no longer a *terra incognita* but a well-understood and fruitful field for the saving of human life.

Time would fail me to speak of the ophthalmoscope, the laryngoscope, the hypodermic syringe, the clinical thermometer, and innumerable instruments which belong to the progress of the nineteenth century. I may conclude what I have to say of the progress of medical science in our day by calling to your minds the discovery of the Roentgen ray, by a professor in the University of Wurzburg, who so lately showed to an astonished world that he could see the skeleton inside the body, through the flesh.

In the judgment of the present speaker the individual, the public at large, and State governments ought to take a positive interest in medical science. There is not a field for investment on this wide earth that will repay the individual, the public, and the State better than is to be found in the most generous treatment of the medical profession. Its wants should be provided for, its demands heeded, legislation pertaining to the public health should be directed by it alone; until the time shall come, even on this planet, when that millennium of happiness shall have been reached which the prophet Isaiah had in mind when he said, "The inhabitant shall not say I am sick." It is perfectly possible for us to conceive with truth of the period when human ingenuity and human skill and human foresight and care, shall be so efficiently used

that no accidents shall occur, and infectious or contagious epidemics shall not prevail, and the individual shall not die prematurely, but when his days are fully numbered. When this day comes, or when its approximation shall be reached, it will be due entirely to the scientific and humane labors of that profession which this academy represents, and to which we have the honor to belong.

THE IMPORTANCE OF ASEPTIC VACCINATION, WITH REMARKS ON VACCINATION IN GENERAL.*

By WILHELM KARL KUBIN, M.D.,

NEW YORK,

ATTENDING SURGEON TO THE GERMAN DISPENSARY; CLINICAL ASSISTANT TO THE SKIN AND CANCER HOSPITAL.

The recent outbreak of smallpox in New York has brought the subject of vaccination very prominently before the medical profession. My object in presenting this paper is to report two hundred and twenty-four carefully studied personal cases which I have observed in my private practice within the past four months; to call attention to the many complications and dangers which follow vaccination; to show by statistics the necessity for vaccination, and finally to emphasize the importance—since vaccination is inevitable—of purity of virus, of proper method of operation, and especially of post-operative control of the patient, which necessarily entails methodical after-treatment.

I shall first devote a few words to the necessity of vaccination. While the vast majority of scientists are agreed as to the protective power of cowpox inoculation, every death following this operation is certain to give rise to agitation hostile to compulsory vaccination. It is not a question as to whether or not these deaths are actually to be attributed to vaccination; but as long as deaths follow this operation, even if ever so rarely, we are not warranted in making the slightest technical error, from the moment of the performance of the operation up to the time of complete healing.

The chief argument for the necessity of vaccination is, of course, based upon the protective power of cowpox inoculation, as shown by voluminous statistics. In order to show that the protection is of the same character to-day as it was early in the century, my statistics are given indiscriminately. The figures here quoted are taken from Hardaway's[1] work entitled "Essentials of Vaccination," from Brouardel's[2] article in the "Twentieth Century Practice," and finally from the current report of the surgeon-general of the United States army.[3] If further evidence were necessary, it could readily be produced, but the following figures should suffice to convince any unprejudiced person.

"In 1802,[1] about four years after Jenner had made public his discovery, a committee of the House of Commons thoroughly investigated the subject, with a view of determining his claims to a national reward, and succeeded in finding only two cases in which smallpox had occurred after properly performed vaccination. . . . Even as late as thirteen years after the practice had been introduced, no fatal case of post-vaccinal smallpox had been recorded.

"In Copenhagen, with over one hundred thousand inhabitants, where vaccination was universally practised, not a single death from smallpox was recorded during the thirteen years 1811–23. In Anspach, Bavaria, with a population of about three hundred thousand, no death from smallpox took place in the nine years 1810–18. Of more than two and a half millions of people vaccinated in France between the years 1804 and 1812, only seven were known to have contracted variola. . . .

"Universal and extended experience furnishes an overwhelming argument for the practice of vaccination, and the farther back we extend our inquiries the more convincing are the proofs. For example, in Sweden, before the introduction of vaccination, the annual death rate from smallpox was 2,050 out of every million of population, while during the forty years 1810–50, it was but 158; in Westphalia, where the death rate from smallpox was formerly 2,643 per million, between the years 1816–50 it fell to 114; in Bohemia, Moravia, and Austrian Silesia it was reduced from 4,000 to 200; in Copenhagen from 3,128 to 286; and in Berlin, from 3,422 to 176. During Mr. Marson's term of thirty years in the London Smallpox Hospital, 15,000 cases of variola were under his charge, and his statistics prove that the unvaccinated died at the rate of thirty-five per cent., while the presumably vaccinated died at the rate of six and one-half per cent.

"When smallpox prevails in a community where some are protected and others unprotected, the influence of vaccination is most strikingly shown. Thus in the Island of Bombay, for the years 1848–53, the smallpox deaths among the general population, the majority of which was unprotected, were 5.8 per cent. of the mortality from all causes, but among the European residents, mostly protected by vaccination, the smallpox deaths were, for the same periods, but one per cent. of the deaths from all causes. In observations made for twenty-one years on four millions of people in Bohemia, it was discovered that the death rate among vaccinated persons who contracted smallpox was $5\frac{1}{16}$ per cent., while on the other hand, the mortality among the unvaccinated who contracted smallpox was $29\frac{4}{5}$ per cent.

"Dr. Buchanan, medical officer of the local government board (England), in 1881 prepared a table of comparative smallpox death rates among Londoners, vaccinated and unvaccinated respectively, for the fifty-two weeks ending May 29, 1881, calculating that the vaccinated persons of all ages living in London, in the twelve months concerned, were 3,620,000, and the unvaccinated of all ages, 190,000 in number. This table reads:

Death rate of people of subjoined ages.	Per million of each age of the vaccinated class.	Per million of each age of the unvaccinated class.
All ages	90	3,350
Under twenty years	61	4,520
Under five years	40½	5,950

"Nothing more clearly exhibits the efficacy of proper vaccination and revaccination than the medical history of the Franco-Prussian war. At that time, according to Dr. Welch, smallpox prevailed to an alarming extent, and both armies were fully exposed to the contagion; but the German mortality was only 263 men, while the French loss was 23,468, although the latter army was at no time more than half the size of the former. The explanation of the marked difference in the smallpox mortality of the two armies lies in the fact, as pointed out by Dr. Welch, that in no country is vaccination carried on with greater care and thoroughness than in Germany."

"Husson and Bousquet[2] were the first to recommend revaccination. . . . It was in Prussia that revaccination was first practised in a way that brought conviction of its value. In that country all soldiers were revaccinated. During the period from 1834 to 1848, out of 425,000 cases of revaccination, positive results were obtained in 198,000, or 46.58 per cent. In these fourteen years there were but 77 cases of

* Read before the Medical Society of the County of New York, March 25, 1901.

variola and varioloid in the army, and among them not a single death. In 1843 smallpox was epidemic in Prussia, but in the entire army there were but 12 cases.

"In Prussia the mortality from smallpox in the year 1835 was 27 per 100,000; in 1872 it was 262. In 1874 vaccination and revaccination became obligatory, and the mortality fell at once to 3.60, and in 1886 it was only 0.39 per 100,000. In 1886 there were 197 deaths from variola in the entire German Empire; in 1887 there were 168, in 1888 there were 112. in 1889, 200, and 58 in 1890, while in 1891 there were but 40 deaths. The number of deaths from this disease in France was 56 times greater, in Austria 60 times greater, and in Italy 97 times greater."

"In 1898,[3] 92 cases of smallpox were reported in the United States army, with 23 deaths, and in 1899, 347 cases, with 84 deaths, a total of 439 cases, with 107 deaths during the two years. Of these cases, 342, with 99 deaths, occurred in the Philippines, the fatal cases constituting 29 per cent. of the total number. Seventy-two cases, with 3 deaths, occurred in the United States, the fatal cases constituting only 4.17 per cent. of the total number.

"That the regular troops were better protected from the infection of smallpox than the volunteers, is shown by the relative prevalence of the disease among the troops in the Philippines in 1899, where large mixed commands operated during the whole year in a dangerously infected country. Among a mean strength of 22,922 regulars there occurred 110 cases, of which 23 proved fatal, while among the volunteers, with a mean strength of 16,358, there occurred 157 cases, 55 of which were fatal. The rate of admission per thousand of strength among the regulars was 4.80, among the volunteers 9.60; and while the death rate among the regulars was only one per thousand men, among the volunteers this rate was 3.36 per thousand."

In addition, I may mention that Brouardel[2] states views similar to mine, of the protective power of vaccination, when he expresses the opinion that a community, in which every individual has been vaccinated and revaccinated, is absolutely protected from an epidemic of smallpox.

It will be seen that the subject matter of my paper deals almost exclusively with vaccination with bovine virus, this limitation being due to the fact that humanized virus has long been a thing of the past in the United States, and its introduction could possess only a historical interest.

So much for the protective power of vaccination, which can be positively proved only by repeated revaccination up to the point of absolute immunity against variola.

The causes of the various untoward results incidental to vaccination may be enumerated as follows: 1. Impure virus. 2. Abnormal or paradoxical course of the cowpox itself. 3. Improper performance of the act of vaccination. This class may be subdivided as follows: (*a*) unclean instruments and hands of operator; (*b*) improperly prepared surface for vaccination; (*c*) imperfect dressing, which will allow secondary infection. 4. Neglect on the part of the vaccinator to exercise supervision and control of the patient until the time of complete healing. 5. Coincident diseases: scarlatina, measles, etc.

1. Impure Virus: The science of bacteriology teaches us that, in theory at least, vaccine lymph is by nature septic—that is, it contains numerous forms of germ life which, however harmless they may be in most instances, are pathogenic under certain circumstances, to say nothing of manifestly pathogenic germs which may be present exceptionally. Until the introduction of glycerinated lymph, bovine virus could not have been aseptic, but as a matter of fact an astonishingly small number of accidents is traceable to impure calf lymph; while, on the other hand, even since the introduction of so-called sterile vaccine, impurities have sometimes crept into the lymph through some neglect on the part of the manufacturers.

I may mention under the head of accidents from impure lymph, in comparatively recent times, the epidemics at Elberfeld[4] and Strasbourg[5]—the latter in 1899—in which the virus was prepared in well-known institutes. In the Elberfeld episode the complication produced was impetigo contagiosa of severe type, even including some fatalities, while the cases which occurred in the vicinity of Strasbourg were of a septic character. In both these episodes, official investigation held the manufacturer of the lymph responsible for the bad results.

As a matter of passing interest I may mention the fact that the parasite of ringworm (tinea tricophytina) has undoubtedly been known to contaminate bovine virus and communicate the disease to the vaccinated person.

"In 1896[6] a German commission, Dr. Koch with others, investigated the best means of preserving lymph, and in that report they state that fresh lymph contains numerous microbes, whose number decreases on the addition of glycerin; thus the commission found the streptococcus destroyed in eleven days, and the diphtheria bacilli in twenty days by this means. They further found that the mixture of glycerin with distilled water could be employed to the extent of fifteen to twenty times the weight of vesicle pulp collected, without interfering with its value for vaccinating purposes. Copeman and Blaxall[6] further found that vaccine could in this way be freed from pathogenic bacteria, as those of tubercle and erysipelas, even when added in considerable quantities."

I cannot help agreeing with other observers, such as Copeman[6] and Henry Wallace,[7] that the glycerinated lymph is preferable to any other.

Through the kindness of Dr. Huddleston, who has charge of the laboratory of the New York board of health, I was enabled to visit the laboratory and learn the manner in which their vaccine virus is prepared for use, which, briefly stated, is as follows: a healthy calf is taken, the posterior abdomen and inside of the thighs are washed with hot water and shaved and washed again, then scarified with superficial linear incisions made with a knife, and over this surface vaccine (cowpox) virus is carefully smeared with an ivory or metal instrument. On the sixth day the area covered with vesicles is most carefully cleansed; the vesicles, technically called "pulp," are picked off with curette, deposited in a small cup and weighed, then ground up, and mixed with two parts of glycerin and one part of sterilized water. The calf is killed and necropsy made by a veterinary surgeon. After it has been shown, through frequent tests by the bacteriologist, that the lymph is free from pathogenic germs, and the veterinary surgeon has reported the calf to have been healthy, the virus is put up and dispensed. (For further details see *Scientific American*, January 19, 1901.) I do not doubt that other manufacturers are just as careful in the preparation of the virus.

2. Abnormal and Paradoxical Course of Vaccination. In order to gain a correct idea of what is meant by this term, we must carefully consider the normal course of the cowpox in man. Vaccinia is, of course, an acute infectious disorder which ordinarily runs a mild and uneventful course; but from various causes —either an undue concentration of virus, unfavorable weather conditions, such as extreme heat or sudden changes in the temperature, extreme youth, delicacy or ill health of the person vaccinated, and, finally, undue specific susceptibility to the vaccine virus, or so-called idiosyncrasy—we may see the cowpox run a severe

course in itself, or again—the course being normal as far as the vaccinia is concerned—we may see some latent or unsuspected disease roused into activity. Dr. Bissel[8] holds the opinion that the bacilli of tetanus may lie dormant in the system until stirred up by some stimulus, such as an accidental cut, when the disease will manifest itself. This theory may be a most important one for consideration.

A very interesting communication was recently made to me by Dr. F. Schwyzer, who had vaccinated eight patients suffering from diabetes mellitus, and observed in several instances gangrene of the skin following the operation. In a number of gouty subjects he has seen deep ulcers as a complication.

The above accidents must be carefully distinguished from all others, since they can hardly be prevented. Under ordinary circumstances we may avoid some by selecting the proper moment and declining to vaccinate certain persons until conditions are favorable. But during epidemics this selection cannot be exercised so carefully.

What is a normal or typical primary vaccination? At the end of the third or fourth day after the traumatic reaction, which usually lasts about thirty-six hours, a red papule appears. On the seventh or eighth day the vesicle is shown on an indurated surface surrounded by an areola, and often diffuse redness. After this the contents of the vesicle become turbid, and the lesion resembles a pustule of rounded or elliptical shape, projecting at the sides and flattened at its centre. The inflammatory areola increases in size, and a transient, diffuse erythema may involve the arm or leg. After that the skin becomes less swollen and the umbilication disappears. Then the scab forms, quite frequently preceded by a rupture of the pustule. Often near the site of vaccination, papules or vesicles are observed, which usually heal without developing further. The vaccine virus may also be carried through the lymphatics or veins to distant parts of the body, and there produce normal vaccinia, although the result at the site of vaccination may be negative. During the course of vaccinia a number of symptoms may manifest themselves, such as considerable induration, extensive redness, enlarged and painful contiguous lymphatic glands, pain and itching, constitutional disturbances, as rise of temperature, malaise, pain in different parts of the body, headache, etc., and, quite frequently, vaccine eruptions. "Albuminuria is present in a considerable number of cases" (Peiper[9]). All these will disappear usually without treatment.

Mere delay in the appearance of the vesicle is occasionally observed. I have recently seen two cases; but the course under such circumstances is otherwise normal.

Peiper enumerates the abnormalities of vaccination as follows: Intensification of local reaction. Axillary lymphangitis. Delayed healing. Defective crust formation.

Ulcerated vaccinia, due to injury, poor care, or secondary infection. The edges are thickened, the margins steep, the granulations spongy and bleeding readily, the cubital and axillary glands swell. The child is restless, often feverish. With further neglect, phlegmon or erysipelas may set in. Rarely ulceration is associated with gangrene.

Hemorrhagic vaccinia, analogous to hemorrhagic variola, is not necessarily a sign of hemorrhagic diathesis.

Hæmophilia: As in any wound in this diathesis, profuse hemorrhage may set in. Vaccination has been known to give the first evidence of an existing hæmophilia.

Keloid: As in any wound or ulcer, keloid may develop; it has no connection with the vaccine.

Protracted fever: A febrile process may accompany the evolution of vaccinia, although Peiper regards this as a pure coincidence due to concurrent bronchitis, bowel troubles, etc.

Vaccinolæ: By this term Peiper characterizes the secondary vesicles which appear about the primary pustule at the height. Sometimes they may be due to auto-inoculation by scratching.

Generalized vaccinia: A disseminated papulovesicular eruption, which is not proved to be analogous to variola. It is said to occur by preference in children with eczematous affections.

Ophthalmic vaccinia: Vaccinolæ appear in the eyelids, the conjunctiva, and even the cornea. The eruption is due to auto-inoculation or inoculation from without.

Accidental vaccination: The members of the vaccinated child's family may inoculate themselves from the vaccination.

Post-vaccinal eruptions: Vaccination simply acts as a general irritant in skins predisposed to dermatoses. There are many varieties, some being rashes such as are caused by certain medicines; in other cases diseases like eczema, psoriasis, and pemphigus appear.

Peiper explains the prevalence of these eruptions by reflex irritation, the poisonous or specific quality of the vaccine, and the absorption of some unknown substance from the pustule.

These vaccinal eruptions have been very ably described during the past year by two physicians, Allen[10] and Sobel,[11] of this city. The cases are illustrated by numerous photographs.

In this connection it is well to emphasize a fact not generally taught, that generalized or secondary vaccinia differs radically from any other post-vaccinal rash or dermatosis in being inoculable in the same manner as a primary vaccination, the product being an ordinary vaccine vesicle.

Before proceeding with the report of certain cases of death and complications in general, which were ascribed to the action of the vaccine itself—it being understood that the virus in such cases was pure, and the course of the vaccination not necessarily atypical—I shall detail the method employed in collecting information as to fatalities and untoward results of all kinds, following vaccination.

I sent a letter of inquiry as to fatal results and complications to the health boards of all the principal cities in the United States, Canada, Cuba, Mexico, and some of the Central American states. As a general rule, the health officers praise the results obtained under their jurisdiction, and take pains to insist that they know of no complications or untoward results worth mentioning. My experience in this respect agrees with that of the royal British vaccination commission,[12] which addressed a letter of inquiry, similar to mine, to all of the European governments and many states or colonies throughout the remainder of the habitable world. The health boards of the various countries reported almost uniformly negatively with respect to bad results or serious complications following vaccination. The few who mention any ill effects explain them by some coincident circumstance having little or no relation to the act of vaccination, quality of virus, or method of performance.

Nothing could be further from my intention than to reflect in any way upon the good faith of these health officers; but it is none the less a fact that the public vaccinators do not have the opportunity to follow up their vaccinations, bad results usually coming first under the observation of private practitioners, dispensaries, or hospitals.

I have also sent similar letters to a hundred (in round numbers) of the leading practitioners in New York City, Philadelphia, Baltimore, and other cities. I must here take the opportunity to thank all these

gentlemen for the uniform courtesy and sympathy with which they have replied to my letters, and for the valuable information contained in their answers. Of course my gratitude also extends to the public officials as well. I have likewise extensively consulted all the literature of vaccination since the date of introduction of bovine virus, and have spent considerable time upon the report of the royal British vaccination commission.[12] A few words upon this latter work may be of interest in this connection.

Collective investigation of the accidents following vaccination has been attempted on a colossal scale by the British government. The work and reports extend over a number of years and are still unfinished. In the absence of any index, synopsis or final summary and conclusions, this vast monument of conscientious effort is almost unavailable for reference or quotation. Some of the data in this work consist of the entire testimony brought out in coroners' inquests, the records of innumerable witnesses examined by the commission in regard to personal knowledge of vaccination, details of fatal cases, accidents, etc., obtained by filling out elaborate blank forms, etc.

Several hours spent in looking over these reports show that the arm-to-arm method is still the prevailing mode of vaccination in Great Britain. Not more than one person in ten, discussed in these reports, appears to have been vaccinated with animal lymph. In a table of two hundred and five fatal cases of vaccination which occurred in the thirty-eight months ending December 31, 1891, we find that but twenty-three persons were vaccinated directly with calf lymph.

In this series of fatal cases the victims, independent of the mode of vaccination, were all very young infants, many but a few weeks of age. Nearly all were children of the poor, with more or less unfavorable surroundings. With scarcely any exception the fatality was due to late infection. The phenomena which followed and led to death consisted of phagedena, purulent infection, erysipelas, and sepsis. We find little or no mention of any rare accidents, occasionally recorded after vaccination, such as nephritis, choleriform diarrhœa, otitis media, tetanus, etc.

Returning now to the notes of severe complications and fatalities which I have collected, I must state that very many private practitioners who replied to my circular letter had experienced or heard of one or more of these unfortunate sequelæ. Many of my lay friends also knew of similar results which had occurred either to themselves or others. At the same time I have found that many cases of this character exploited by the daily papers are untrustworthy, and it has happened more than once that an autopsy has revealed that death following vaccination could, by no possibility, have been due to that operation, even in the most indirect manner. In one of these cases the postmortem revealed a tumor of the brain, which was responsible for the grave cerebral symptoms that followed vaccination (Huber[13]).

In this connection an account of the following episode, which occurred in Denver, may be of interest. A death was reported as due to "septicæmia following vaccination." The health department upon receiving this report stopped the funeral proceedings and ordered an autopsy. It was learned that the child had been vaccinated three years before its death. Autopsy revealed a clean, healthy vaccination scar, and developed the fact that death was due to empyema from neglected pneumonia, the child having been under the treatment of Christian or divine scientists.

I shall now consider some of the details of untoward results of vaccination. Following the classification of accidents, etc., which I have proposed, I have already discussed the first two causes, viz.: impure virus and abnormal course of the vaccinia. But since it is often impossible in practice to explain the precise rationale of these accidents, I prefer to present the facts that I have collected in the manner in which they were secured. I shall therefore take up the causes of bad results in connection with the individual cases, and shall review, in the order named, cases from the literature, correspondence, and my own practice.

Cases from the Literature.—*Boston Medical and Surgical Journal.*[14] Several years ago the editor of this periodical called attention to the large number of severe complications of vaccination which occurred in a certain locality, presumably in New England. All the physicians in this territory reported cases of lymphangitis, cellulitis, fever, and other evidences of sepsis. There were no fatalities, but in one case death was threatened. The lymph was at first blamed, as it had all come from one institute. It was finally, however, decided that, owing to the interval which had elapsed after vaccination (twelve days and upward), the cases were to be ascribed to secondary erysipelas from scratch inoculation.

Chambard-Henon.[15] A case in which the vaccine pustule became hemorrhagic on the seventh day, with a scarlet (purpuric?) eruption on the arm. On the fifteenth day, albuminuria developed, followed by nephritis. The patient was anæmic.

Dauchez.[16] A child two years old, who had formerly suffered from diarrhœa and marasmus, but had apparently recovered, developed, on the fifth day after vaccination, fever, vomiting, pains in the limbs, etc. On the seventh day the vaccine pustule, hitherto normal, became inflamed, with axillary adenitis. On the eighth day a choleriform condition fully developed, with cyanosis and algidity. Death occurred on the tenth day.

Davis.[17] A child aged seven and one-half months; its mother subject to erysipelas. The vaccination was normal up to the seventh day when erysipelas developed on the site of the pustule and over the surface of the body. The erysipelatous affection did not progress further, but double lobar pneumonia set in, followed by death on the ninth day after the appearance of the erysipelas.

Dimon.[18] (1) A boy aged nine years. Tetanus was found fully developed twenty-one days after vaccination. The site of vaccination was then occupied by a large ulcer covered with prominent granulations and thick pus. The arm was swollen, with ascending patches of erythematous inflammation and axillary adenopathy. The case ended fatally. No other injury was present. (2) A case of fatal septicæmia following vaccination. No particulars are given.

Drury.[19] A discussion by a local medical society in Cincinnati. The members reported cases of abscesses, ulceration, gangrene, erysipelas, and otitis media following vaccination.

Engelmann.[20] (1) A nursing baby with marasmus developed phlebitis and pyæmia with fatal results. The autopsy revealed thrombosis of the cephalic vein near the site of vaccination; also multiple subcutaneous abscesses. (2) A case of nephritis, uræmia, and death following vaccination.

Ensign.[21] A pregnant woman, nearly at term, was vaccinated; pain and inflammation soon developed with a large axillary abscess which discharged pus. Death occurred in two months, the child having been delivered two days before. The upper arm was said to have been in a state of necrosis at death.

Epstein.[22] Two cases of acute hemorrhagic diathesis (purpura) developing about the fourth day after vaccination, which in itself was normal. Both patients recovered.

Farrar.[23] A child aged five months, not well developed. Vaccination appeared normal, but the scab did not separate, and the pus burrowed beneath. A rupial

crust formed, with resulting deep ulceration, but no further local reaction followed. While the ulcer was healing kindly, death took place without apparent cause, seven weeks after vaccination.

Fox.[24] He has seen three cases of lupus develop in vaccination scars, and cites two similar cases reported respectively by Besnier and Lennander.

Gaucher.[25] A child vaccinated when nineteen days old. The pustule was normal, but on the ninth day generalized vaccinia developed; the temperature was 40.5° C.; vomiting, cyanosis, and death from asphyxia followed. The autopsy revealed appearances usually seen in death from acute infectious diseases.

Hawes.[26] Death of a three-year-old girl from sepsis about three weeks after vaccination.

Holt.[27] A previously healthy child developed, two weeks after vaccination, a pustular eruption, double axillary adenopathy and suppuration of the glands in the opposite axilla, soon followed by acute bronchopneumonia, which proved fatal. The vaccination site had an unhealthy look.

Hutchinson.[28] Two cases (one originally reported by C. Lucas); late gangrenous ulcerations of the arm occurred, with fatal terminations.

Luce.[29] Two fatal cases of early erysipelas followed by gangrene.

Mazzoni.[30] In a series of eight cases of vaccination, redness appeared within two hours, followed by erysipelas, phlegmon, and suppuration. One child died three weeks later, the rest recovering after severe illness; the vaccination did not take.

Perl.[31] A case of acute parenchymatous nephritis following vaccination, on the fifth day. The child recovered. The urine contained one-half per cent. albumin, casts, blood, etc.

Peters.[32] A case of late erysipelas followed by gangrene and death. In the discussion of this paper, Emery related a case of formation of a deep ulcer at site of vaccination, with abscesses in the axilla and up and down the arm. The child was known to have scratched the vesicle with its nails. A sudden change to cold weather occurred at the same time. The child recovered.

Pooley.[33] A case of a young man with severe local and general symptoms following vaccination. He was laid up in bed for a month, and upon getting up found his arm was paralyzed (motor and sensory). He had pains referred to the arm. His hand sweated profusely. This patient recovered in time.

Schaeffer.[34] In a child aged three and one-half years, inflammation of the arm, fever, and diarrhœa set in on the eleventh day after vaccination. At a later period, sloughing occurred at the site of vaccination, leaving a large ulcer, which slowly healed. Schaeffer knows of a fatal case in the practice of a colleague; no details are given.

Simmons.[35] On the ninth day after vaccination a child became feverish, and developed adenopathy of the arm-pit and neck and a general measly eruption. The arm appeared to be paralyzed, was swollen and dotted with ecchymoses. The scab was dark red. The parotid and submaxillary glands were enlarged, along with the lymphatics, with threatened suppuration. Convulsions appeared, and the child died on the third day of the attack and the twelfth day after vaccination.

Toms.[36] A child aged five and one-half years, scrofulous (suppurating adenitis and strumous keratitis). The after-treatment was neglected and several chances were given for late infection. On the eighteenth day the vaccination site ulcerated to the size of a half a dollar, with a fetid and sanious discharge. No swelling of the arm or axillary glands occurred. There were fever with a temperature of 100.5° F., and malaise. The ulcer began to improve under treatment, but on the twenty-fourth day after vaccination, tetanus set in; it was of a mild type and might have ended in recovery had not fatal œdema of the lungs set in. No tetanus bacilli were found in the pus of the ulcer. The child had already developed an aphthous sore mouth after vaccination; this may have been the source of the tetanus.

Cory.[37] Two cases of generalized vaccinia ending in a multiple gangrene, one of which terminated fatally. The arm-to-arm method was used in the fatal, and probably in the other case.

Bieser.[38] A child aged three and one-half years died from acute septicæmia, on the eighth day after vaccination.

Sturmdorf.[39] A girl thirteen years of age had acute primary osteomyelitis of the femur, which required operation. Later investigation revealed the fact that the patient had been vaccinated on the diseased leg ten weeks previously, with subsequent cellulitis, which had disappeared when the writer saw her for the first time.

In addition to the preceding cases I append an interesting series of untoward results from the recently issued report of the surgeon-general of the United States army.[3]

1. Septicæmia following vaccination; recovery.

2. Abscess of left axilla and pectoral region, due to vaccination; resulting in contraction of muscles and fasciæ, impairing the use of the arm.

3. Death from tetanus, resulting from infection by vaccination.

4. Erysipelas following vaccination; recovery.

5. Neuritis of the left arm following vaccination; later, false ankylosis of the left elbow from the same cause. The patient was able to return to military duty for a few weeks, but then lost both power and sensation in the arm. He was discharged from service for paralysis of arm and forearm.

6. A patient was admitted to the hospital, suffering from vaccinia. Two days later synovitis of the right knee developed. Later synovitis of the left knee appeared, which became chronic. He was discharged from service. The fact is mentioned of an axillary abscess following (a second) vaccination. The abscess was incised and curetted, but fatal septicæmia developed.

7. Fatal septicæmia following vaccination.

8. Vaccination followed by abscess of the left axilla. Fatal septicæmia followed.

9, 10, 11. Three cases of fatal septicæmia sequent to vaccination.

12. A colored soldier vaccinated with all aseptic precautions. Seventeen days later he was reported sick with first symptoms of tetanus, and died two days later.

It should be stated that these eight deaths in the army, from vaccination, are all that are reported in a total of perhaps 350,000 cases.

It is not claimed that the preceding cases from the literature exhaust the number which have been placed upon record. Others could readily be found in such standard works as those of Hardaway,[1] Peiper,[9] Nothnagel,[40] Brouardel[2] (in "Twentieth Century Practice"), etc. It must further be borne in mind that many cases of accidents following vaccination have been reported, in which the reporter fails to state whether the virus used was animal or human. These cases have been disregarded in my paper. Several cases of tetanus might otherwise be added—one reported by Dr. Berkeley,[41] and two in the Island of Cuba. Dr. Berkeley's case was in a man aged forty. A deep indurated ulcer appeared in the site of vaccination. Tetanus developed in three weeks from the operation and resulted fatally. With regard to the tetanus cases collected I find that nearly all occurred in the United States.

The fact should again be emphasized that this paper

has been limited to vaccination with animal lymph, because the use of this substance has become established in this and many other countries, and to speak of accidents in the past which have followed the use of human lymph is to introduce an element of uncertainty which has now been eliminated. At the same time it is just to admit that very many severe complications and fatalities of a past age probably occurred independently of the kind of virus used, having been due to improper vaccination, neglected after-treatment, etc., at a time when asepsis was not dreamed of. It is obvious, however, that we cannot make use of these cases, for vaccinators of a past generation have stated that erysipelas was much more common when humanized virus was used.

Cases Obtained by Correspondence.—Notes of a few cases have been sent to me by public officials. I may here state that a number of health officers of cities make praiseworthy efforts to follow up their cases of vaccination, and thus guard against the possibility of secondary infection; these men attribute the excellence of their records to this and other aseptic precautions.

Three fatal cases of tetanus and one fatality from gangrene and septicæmia have been reported to me by health officers. The latter case was probably in a patient vaccinated on shipboard. A case of meningitis, which developed two weeks after vaccination, was also reported to me by the health officer of a western city. This patient recovered.

The cases communicated to me by private practitioners were, in all but a few instances, of patients vaccinated by some person other than the one reporting the case.

Numerous reports have been received of cases of erysipelas, lymphangitis, phlegmon, gangrene, and other manifestations of local sepsis, while there were others of general septicæmia, meningitis, tetanus, and pneumonia, a number of which ended fatally. These cases are recapitulated briefly with the initial of the observer's surname.

B——. Death from sepsis following vaccination.

S——. Death from septicæmia a few weeks after the opening of an abscess of the axilla, following vaccination. A second abscess had formed meanwhile. The patient was aged fourteen months. An abscess formed ten days after vaccination.

O——. Death from general infection following vaccination.

von G——. Three cases of septicæmia in dispensary patients, one complicated by extensive gangrene of arm. No fatalities followed.

K——. Death from septicæmia in a child aged six weeks. Pyæmia in a child aged six weeks. Pyæmic abscesses in the joints and kidneys (pyuria). The pock had begun to suppurate profusely in the second week, and the arm had thereupon been tightly bandaged.

G——. Before 1885 he saw many cases in dispensary practice—erysipelas, axillary abscesses which required incision and drainage, and other complications.

A——. Several cases of streptococcus pneumonia, one with a fatal termination. Also cases of erysipelas and pseudo-erysipelas; glandular abscesses in the axilla, neck, and groin (the latter after vaccination on the leg).

J——. Before the days of aseptic vaccination he saw many cases of erysipelas, ulceration, and occasionally diphtheritic infection of the vaccine pustule.

M——. He saw cases of erysipelas after vaccination, some so severe as to involve the entire surface; no fatalities followed.

M——. Death from general erysipelas followed by convulsions and meningitis. A child eight months old; erysipelas appeared nine days after vaccination.

H——. Severe erysipelas in a baby ten months old. The infection began at the site of the vaccination (on the calf), and extended over both lower extremities. Recovery occurred in three weeks.

C——. Death from tetanus. A child aged five years, with tuberculous antecedents. Tetanus appeared three weeks after vaccination. All instructions regarding the care of the vaccine pustule had been disregarded. A handkerchief had been bound around the arm and left *in situ* three weeks, causing a foul wound.

F——. He saw an ulcer of the arm as large as a silver dollar, due to vaccination seven weeks previous.

J——. A case of gangrene in the site of vaccination, with severe pain in the brachial plexus.

Z——. A case of suppurating axillary glands requiring removal, also a chain of glands beneath the pectoral muscles, and later, otitis media. The patient has not yet recovered.

S——. A case of severe lymphangitis following vaccination on the thigh, in the third week. The parents of the child had been very indiscreet in the after-care of the pustule.

M——. A case of extensive phlegmon of the entire arm, terminating in a large deep-seated abscess of the lower cubital glands. Several cases of suppurating axillary glands.

M——. A case of phlegmonous cellulitis of the arm, involving the axillary glands; it required incision and drainage. Also two cases of general furunculosis following vaccination, involving the trunk, neck, and occiput.

C——. A case of generalized vaccinia of severe type; recovery occurred in about six weeks.

G——. A case of severe universal papular eruption, following a vaccination, with severe local reaction, dermatitis and lymphangitis, rise of temperature; the general behavior was that of an intoxication. Recovery followed.

S——. A case of acute osteomyelitis in a child aged two years, of scrofulous stock. Three days after vaccination the child became very ill, with severe constitutional disturbance, fever, the arm swollen, the axillary glands enlarged, and a stiff neck. He was ill for ten days, and the vaccination pustule healed in three weeks. Twenty-three days after inoculation, osteomyelitis began at the lower extremity of the right fibula; followed by intermuscular abscesses and suppuration of the ankle-joint. Streptococci were found in the pus. The child was operated on and recovered.

O——. A ten-months-old baby with a scrofulous history, three and one-half weeks after vaccination developed septicæmia, followed by septic pneumonia and death. The scab had been torn partly off. O—— also had three cases of erysipelas through secondary infection, one quite a severe case, but all ended in recovery.

K——. He saw a man twenty-four years of age, who had been vaccinated by his mother (not a physician). About ten days later a large abscess developed in the axilla, which required operation. The patient recovered in about six weeks.

S——. He saw two cases of suppurative lymphadenitis, both occurring within five and seven days from the period of the first inoculation. Another girl, seven years of age, on the eleventh day after vaccination had a deep excavation at the site of the inoculation, with pus and axillary adenitis; her temperature was 104.5° F. The next day, otitis media purulenta acuta developed and three days later, streptococcus pneumonia. Recovery followed.

The general literature, as well as the notes of my correspondents, contains accounts of many anomalies of vaccination which have not thus far been mentioned, because they were not of a serious character. Some of them may be briefly alluded to. The most interesting is the so-called "raspberry vaccination," a vas-

cular fungoid excrescence which sometimes results from imperfect vaccination or failure to take. It is believed to be due to the use of degenerated lymph.

My friend Dr. W—— has sent me notes of two cases which were recently seen by him. Both patients were vaccinated at the same time with ivory points, all aseptic precautions having been taken. Three days later several small, bright-red, separate papules appeared at the site of vaccination, and gradually increased in size, without the formation of an areola. One week after the first vaccination, both patients were revaccinated with board-of-health (glycerinated) lymph, on the same arm as before, and each vaccination took in the normal way. The raspberry vaccination continued to increase in size, so that, in one case, the papules coalesced into one large, elevated, bright-red mass resembling keloid, and itching severely. The normal vaccination healed, while the raspberry vaccination was still active, although the latter finally shrank (in one case only after seven weeks), crusted, and scabbed off.

Dr. Morrow[42] once published a classical account of these raspberry vaccinations.

A troublesome sequel of vaccination, which is fortunately of rare occurrence, is the formation of keloid scars. According to Hutchinson,[43] this accident may be associated with a prolonged healing-process.

Many of my correspondents have sent me interesting reports of various dermatoses which they have encountered after vaccination, but as these sequelæ cannot be regarded as of a serious nature, I shall omit enumerating them. I take this occasion to thank these gentlemen for their courtesy in sending me this material, which plays so important a part in my consideration of the anomalies of vaccination.

In this connection I may mention an experience, notes of which were sent to me by my friend, Dr. B——. An infant aged three months, with hereditary syphilis, was vaccinated on the arm. One week later a syphilitic psoriasis appeared on the palms and soles, with mucous patches of the anus. After the vaccine pustule, which ran a normal course, had finished scabbing, its base assumed the appearance of an indurated chancre. In this case an inoculation with syphilis might have been attributed to the vaccination, had it not been for the complete history of the case. Similar cases of spurious vaccination syphilis have often been reported, and are undoubtedly the means of causing hostility to vaccination among the uninformed.

Before proceeding with my own cases, I may mention some facts which came to my knowledge through a patient, who feared to let me vaccinate her on the leg because of unfavorable results that she had seen among her acquaintances, while others among the latter, vaccinated on the arms at the same time, experienced no trouble. In one instance, a young woman was vaccinated on the calf by a member of the family, who was not a physician, and who used an ivory point. Absolutely no precautions were taken. The leg became so sore that the woman had to maintain a recumbent position for two or three weeks. In a second case a young woman was vaccinated just below the hollow of the knee, by a prominent physician who also used an ivory point. Some aseptic precautions were taken, but no protection was used. Great soreness followed, with the formation of a deep ulcer. The patient was laid up for an entire winter. One year later the woman became an epileptic (no heredity), with attacks of the nocturnal type. The scar on the leg was excised, without relief. In the third of these cases, a girl of eight years was vaccinated above and back of the knee, by a physician. Some aseptic precautions were taken. A severe local reaction followed, with malaise and a general eruption. The patient was confined to the bed, with ice to the leg; profuse suppuration followed, with an ulcer at the point of vaccination. Healing was not completed until two months had elapsed, and the child, originally robust, has been delicate ever since.

Personal Observations.—I shall close my citation of individual cases, with an account of the complications of which I have personal knowledge. Only one of these individuals was vaccinated by myself. I am not now including my two hundred and twenty-four vaccinations of the last four months, which I shall discuss separately.

M. B——, a girl of thirteen years, came to the German Dispensary last January, with an abscess of the under surface of the arm, about two inches below the level of her vaccination. By pressing upon the swelling, pus escaped freely from the site of the inoculation, which had an unhealthy look. She stated that she had been vaccinated as a baby (two scars were still visible), and again four weeks previously. The arm was not prepared beforehand, and no protection whatsoever was employed. The arm having become sore, she was obliged to go to a physician, and afterward to the dispensary, where she came under my observation. Incision of the abscess and drainage brought about rapid recovery.

W. D——, aged twenty-three years, was vaccinated in 1891. No dressing was used, and the scab adhered to the shirt sleeve. Whenever he dressed and undressed, the scab was detached. His arm did not heal until about four months had expired.

H——, aged thirty-five years, was vaccinated in 1884 on the left arm, with negative result, but ten days later generalized vaccinia of the whole body occurred. He recovered within sixteen days. This patient was under the impression that he had passed through an attack of smallpox.

J. R——, aged thirteen years. When seven months old he had typhoid fever; at two and one-half years scarlatina, and six weeks later, measles. An attack of nephritis with hæmaturia followed the scarlatina. The kidney trouble lasted a year and ended in recovery. The patient had the mumps when three years old, and a second attack of measles at the age of four years. From that time he was well until vaccinated. This operation took place in 1897, when the patient was ten years of age. The arm was not prepared, and a felt shield with uncovered perforation was used. I saw him first nine days later, when an abscess developed at the site of vaccination, with pain and redness of the arm as far as the elbow. Pain, redness, and swelling then developed at the upper end of the lower third of the left tibia, at the site of a fracture which had occurred three years previously. All these symptoms disappeared in about three weeks. Eight months later, osteomyelitis developed in both tibiæ. He recovered in about a month, without operation.

Mrs. L——, aged thirty-one years, had been vaccinated in 1870. In 1893 her baby, aged about one year, was vaccinated on the left arm. While the mother held her child against her left breast, the infant, whose vaccination was not protected, scratched her below the left ear, and produced a normal vaccination. A large scar resulted, and is still noticeable.

J. F——, aged thirteen years. This is the only individual in the present series of six cases who was vaccinated by myself, the operation having been performed December 5, 1897. The arm was carefully cleansed and a felt-and-wire shield applied. On the seventh day a perfect vesicle and areola were present. Three days later erysipelas appeared. The boy stated that in the course of some rough play at school he had received a knock over the site of the vaccination, which displaced the shield. Infection most likely resulted at that time, as the shield was not aseptic. This patient recovered readily. Since that time I have used aseptic gauze and adhesive plaster for dressing, and have had no unfavorable results.

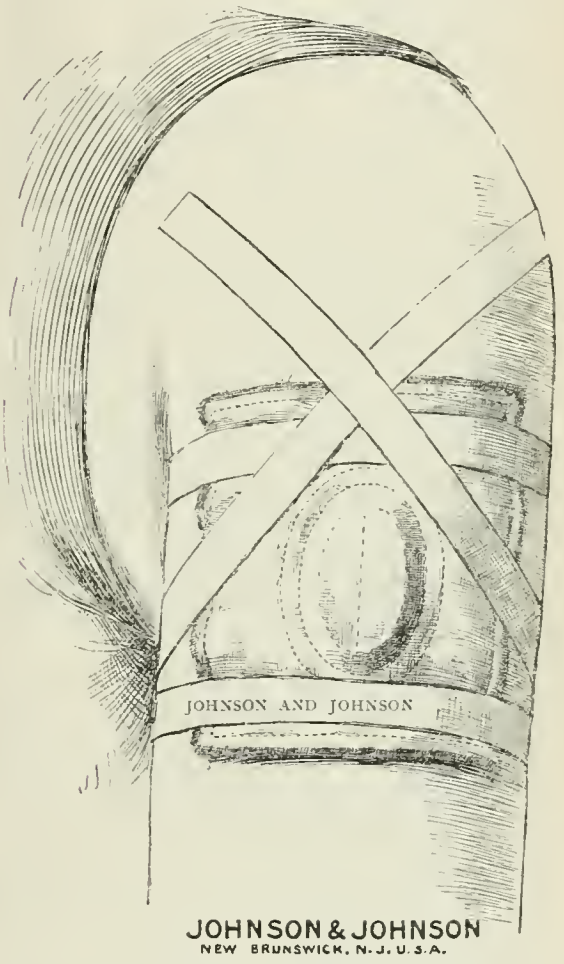
In all my cases, with the exception of three, I have employed the lymph supplied by the New York board of health.

I now come to the most important part of my paper; namely, the operation of vaccination itself, and a consideration of how to make it aseptic. Not only the laity, but the physicians as well, are prone to underrate the importance of this procedure. It is absolutely essential to the completeness of a vaccination that the patient return for inspection at the expiration of the first week following the operation. This has a twofold advantage. First, the physician has an opportunity to determine whether or not the vaccination has been successful; for the laity are no judges of a positive result. This matter is of vital importance to the patient and the community, for if the result has been negative, the patient, who perhaps may have had some sort of local reaction, with a sore arm, may fancy himself protected, and therefore expose himself carelessly to the smallpox. Second, this inspection of the vaccination will likewise give the physician an opportunity to recognize complications at an early stage. Of course, if the first inspection proves the result to be negative, the patient should be seen a second time, to make sure that the case is not one of delayed vaccination; and the physician should make it a rule to keep the patient under observation until the wound has entirely healed. He should watch these cases with the same care and sense of responsibility as any of his major operations. It is self-evident that no one but a physician should be allowed to vaccinate.

I am well aware that there is nothing new in these suggestions, which have been made in all standard works on vaccination, such as those of Peiper,[9] Hardaway,[1] Immerman[40] (in Nothnagel's "Handbuch"), Brouardel[2] (in "Twentieth Century Practice"), and others; and which have also been faithfully carried out by many practitioners. But it is none the less evident that the occurrence of unfavorable results justifies the repetition of these suggestions.

The technique which I employ is as follows: the skin is made as nearly aseptic as possible by scrubbing it with soap and water, using an ordinary surgical brush. Recently I have used synol soap, which I find to be powerfully cleansing and convenient, while at the same time it does not interfere with the success of the inoculation. I next treat the skin with alcohol, then with ether, again with sterilized water, and finally dry the surface with sterilized gauze or cotton. I scratch the skin superficially over an area of about one-quarter of an inch, making four or five parallel scarifications, and as many more across the first at a right angle, causing no bleeding if possible. The lymph is conveyed to the scarifications and thoroughly rubbed in with the spade which, as well as the needle, should be furnished sterile by the manufacturers. Before I devised my shield I allowed the exuded serum to dry exposed to the air. After drying, I cover the wound with an aseptic gauze compress, fastened with strips of adhesive plaster. I give the patient very strict instructions as to the importance of returning for inspection and possible after-treatment, and not to disturb the dressing. With very few exceptions my patients returned, and in no case did I see the compress adhering to the vesicle, nor did I observe any irritation of the skin from the plaster. Moreover, the dressing seldom became disturbed, although some strips of plaster may have become partially loosened. But after the pustule had formed, I have found in quite a number of cases that rupture took place. I believe that the membrane covering the pustule is much more delicate than that covering the vesicle; and for that reason rupture will more easily occur in the former. When the pustule ruptures, the contents are absorbed by the gauze, producing thereby a very characteristic and offensive odor. If this dressing remains unchanged, there is danger of secondary infection and dermatitis. In a few cases, adhesion of the gauze was noticed. In changing the dressing when adhesions formed, I did not disturb the scab, but cut around it and removed some of the layers of gauze, applying a fresh dressing over the remainder. With this method I obtained most gratifying results.

Notwithstanding the fact that my results have been excellent, I still think there may be room for improvement in several directions. The vaccine tube might be so weakened by a scratch with a file at either end that it would break more readily, and it might also be well to handle it, while breaking, with the fingers protected by aseptic gauze; otherwise the lymph might become contaminated by the fingers or nails.



Since Hausmann[44] has shown that lymph blown from a tube may be contaminated with epithelial cells from the mouth, this possible source of infection should be obviated by using the small finger bulbs supplied by Mulford and others.

I shall now consider the possibility of germs from the air falling upon and infecting the site of vaccination during the drying of the serum and lymph upon the scarified and inoculated area. To avoid this source of danger, I have devised my aseptic shield, which can be immediately applied over the site of the inoculation, and retained up to the first day of inspection, when it may be loosened at the bottom and immediately fastened again with plaster. Should it be found soiled by the discharge from the pustule—which happens occasionally—a new shield must be substituted.

My shield consists of eight layers of gauze, each three and three-quarter inches long and three and one-quarter inches in width, having enclosed in the centre a wire net two inches long and one and one-half inches wide, with a height of one-half an inch. Five asep-

tic strips, each one six inches long and one-half an inch wide, accompany every shield, four of the strips to be used in the primary adjustment of the shield, and one for reserve to be used when inspection is made. This all reaches the physician in an aseptic condition. Under this device the scab will remain undisturbed by friction of clothing, and healing may go on to completion under a single shield.

This last innovation I can recommend the more highly because I have already employed it in quite a number of cases.

During November and December, 1900, and January, 1901, I vaccinated two hundred and twenty-four individuals, and kept a careful watch over my cases, making all necessary notes. This report I pass around for your inspection.

All twenty-six primary vaccinations took, and in addition, one hundred and eighty-three of revaccinated cases, making in all a total of two hundred and nine out of two hundred and twenty-four. There were ten cases with constitutional disturbances—generally about the seventh or eighth day—only two patients being confined to bed, one for three days. This last was a young lady of twenty-two, who was vaccinated first in 1879 with positive result, and not again until 1900. She had quite severe constitutional disturbances, which I first thought to be the grippe. Her temperature was 103.2° F. Her vaccination was upon the thigh, and she had enlarged and painful inguinal glands. As a child of five and seven years of age, she had enlarged cervical and inguinal glands on both sides.

The other, a little girl five years of age, vaccinated on the calf of the leg (primary vaccination), had considerable induration and redness after the eighth day, and constitutional disturbance lasting for several days; she was confined to bed for one day.

There were twenty-six cases of enlarged and painful axillary glands, and four cases in which the inguinal glands were similarly affected. The total number of thigh vaccinations was seventeen.

Out of twenty-four cases of vaccination on the calf, only one was followed by enlarged and painful inguinal glands.

There were eleven cases of considerable induration and redness; and four cases of considerable cellulitis, requiring moist dressings, these four having been the only cases requiring treatment of any sort, to which they responded promptly.

I had three cases in which deep ulcers developed, but as no other complications were present, healing was not greatly retarded.

There were two cases of auto-inoculation. A young lady of eighteen, who was vaccinated on the calf of the left leg, inoculated the end of her thumb and middle finger of the right hand and index finger of the left hand. Her sister, aged sixteen, vaccinated in the same way, inoculated the point of the thumb and middle finger of her right hand, the left side of the face a little below the lips, the inside of the left leg just above the ankle, and the index finger of the right hand near the knuckle. These young ladies disregarded my instructions by disturbing the dressings and scratching the skin at the site of vaccination, in the third week following the operation. Many cases of auto-inoculation on different parts of the body, as at the anus, vulva, etc., have been reported.

In all complications except the adenitis and auto-inoculation cases, it was noted that the vaccination was either primary, or a revaccination following an unsuccessful, or very remote successful vaccination.

In one case, a boy five years of age, suffering from eczema on his face and hand, was vaccinated by me for the first time in his life, in December, 1900. The vaccinia was normal, and afterward the eczema seemed to improve. He was vaccinated for the reason that his father's occupation exposed him to the smallpox contagion.

One patient had severe smallpox in 1871. He had been vaccinated in 1863, but I have some doubts as to whether the operation was successful. My result in this case was negative. In three other cases the patients had had smallpox after successful vaccination, but of a very mild type. One patient was a lady aged sixty years, vaccinated successfully in 1840, and again in 1888; in 1894 vaccination was negative, and in 1900 positive again. She had a mild attack of smallpox in 1888, six months after successful vaccination.

One young lady aged sixteen years was vaccinated with positive result in 1884; with negative results in 1894 and 1896; she was vaccinated by me in 1900 and 1901, on different parts of the body, with negative results. She had a mild case of smallpox in 1890.

One girl aged eleven years was first vaccinated in 1890 with positive result, in September, 1900, at school, with negative result, and by me, successfully, two months later. Quite a number of my cases took in patients who had also been successfully vaccinated within ten years, and even up to within four or three years.

I have recently written to the authorities in charge of the smallpox hospital of New York City, for information as to whether the cases of severe variola during the present epidemic had been vaccinated, and if so, when; but unfortunately it was impossible to obtain a report. My reasons for this inquiry lay in my belief that these patients had either not been vaccinated at all, or had not been revaccinated during long periods.

In conclusion I desire to suggest that a national law for compulsory vaccination and revaccination, such as exists in Germany, and similar to those adopted in many other countries, should be passed. I would also recommend that a knowledge of the importance of vaccination should be taught in the schools, so that when children become adults, it will not be so difficult to teach them the importance of revaccination. For, although I have cited so many fatal and severely complicated cases following vaccination, it must be remembered that they are collected from many millions of persons vaccinated, and are an insignificant percentage when compared with those unvaccinated persons who have died from the effects of smallpox.

I would also like to emphasize the necessity of giving special instruction in vaccination in all medical colleges.

Although the number of cases reported by me is comparatively small, the results seem to justify the conclusion that, if the above instructions are carefully adhered to, serious complications will be of rare occurrence, and the anti-vaccinationists may have even their last foothold removed from under them.

THE FIELD FOR ETHYL CHLORIDE NARCOSIS.[1]

BY MARTIN W. WARE, M.D.,
NEW YORK,
ATTENDING SURGEON, GOOD SAMARITAN DISPENSARY.

THE strife that is still waging between the advocates of chloroform and ether, or combinations of both with still other adjuvants, will hardly be further complicated by the advent of ethyl chloride as a general narcotic; for it is not in its competition with the aforesaid anæsthetics in the field of major surgery that it has to win its honors. It is in the realm of minor surgery that its uses have thus far been exploited, with such signal success that I was impelled to give it an extended trial in two hundred instances, embracing most operations in the domain of minor surgery, and applied to individuals varying in age from infancy to old age. The history of this agent must needs be a preliminary to my personal experiences.

As a matter of passing interest I would state, on the authority of chemists, that in the dark ages mention is made of an alchemistic product known as "vinum salis," produced by the distillation of salt and dephlegmated alcohol, which had narcotic effects on imbibition. Again, it is a matter of record that about the middle of the eighteenth century a German chemist, Woulfe, made a product known as light hydrochloric ether, to distinguish it from the heavy hydrochloric ether, the so-called "Dutch liquid," which in the early part of the nineteenth century, at the time when chloroform and ether first came into use, was also employed as a general anæsthetic by English and German physicians, and spoken of as chloride of ethyl (chloric ether). But a careful study has convinced me that much uncertainty prevailed as to the exact composition of the chloride of ethyl used. Perhaps the English surgeon Snow (1852) did use a pure product, for he says: "The first quantity obtained from Mr. Mason of the 'Paris liquid' consisted chiefly of monochloruretted chloride of ethyl mixed with a certain portion of the bichloruretted and terchloride product, but I was able by distillation to separate so much of the monochloride product as to enable me to administer it to twenty-two patients." Snow died while writing this sentence, and this therefore closes his observations. Neither Langenbeck, nor Steffen, nor Liebreich used any products analogous to the modern ethyl chloride. They speak of ethylenchlorid, or ethylidenchlorid and ethidenchlorid. These are of entirely different origin chemically from the monochloride of ethyl (C_2H_5Cl).

The latter is the chemical title of the agent hitherto used for local anæsthesia, and is the subject under consideration. My experiences were obtained with ethyl chloride. It is a colorless, mobile liquid, having a peculiar, pleasant odor, and a sweetish, burning taste. It does not solidify at −29° C., boils at 12.5° (Regnault), at 0° possesses a specific gravity of 0.9123 (Pierre), and its vapor density is 2.219 (Thenard). It is but slightly soluble in H_2O, though dissolving rapidly in alcohol.

In 1892 Dr. H. C. Wood, writing in the *Dental Cosmos*, says he could not induce anæsthesia with ethyl chloride by the ordinary methods. He then resorted to the administration of it in a concentrated form, with the tracheal cannula, but concludes that it is fugacious and so dangerous that he believes "it is probable that if it should come to be employed in practical medicine as an anæsthetic, there would be a record of sudden deaths through cardiac failure proportionately even more numerous than with chloroform." In 1894 Schleich, concerning his experiments, says: "We have proven that ethyl chloride, boiling at the room temperature, evaporating at once, acted more violently on animals than the other anæsthetics, and because of the higher boiling-point and slower evaporation of the latter, greater quantities of ethyl chloride entered the lungs." In Schleich's experiments the vapors were given under a bell jar. In like manner, Wood administered ethyl chloride in a concentrated form, and therefore animal experiments of either are not tenable for ethyl chloride as a narcotic in human beings. Subsequently, Schleich admits a more rapid recovery for the animal asphyxiated with ethyl chloride than with the other anæsthetics. Soullier (1895), of Lyons, was the first to administer the ethyl chloride under the most auspicious clinical conditions, and he tells us that in the hospitals at Lyons 8,417 cases were treated, without any direful consequences. Two different accounts leave some doubt whether his was a pure product, though in the first article he emphasizes this point. It was, however, the experiences at the clinic

[1] Read before the Surgical Section of the New York Academy of Medicine, January 14, 1901.

in Innsbruck, exploited by Lotheisen, Ludwig, and Wieser, that gave the real impetus to the use of ethyl chloride as a general narcotic. Cognizance herein is taken only of the experiences of surgeons as to the efficiency of this agent as a general anæsthetic, and up to the moment of writing, including the aforesaid cases of Soullier and 2,550 cases collected by Lotheisen, together with 40 cases recorded by Dr. Tuttle and 200 cases of my own, we have a total of 11,207 narcoses. Bearing on the fatalities, Lotheisen recently puts on record a death in his own experience, thus narrated: A male laborer, aged forty-one years, alcoholic, having an ulcer of the leg, was about to have the operation of Krause's transplantation performed. After three minutes, 10 gm. of ethyl chloride having been used, the patient suddenly became pulseless and stopped breathing. Autopsy: Excessive arteriosclerosis of the coronary artery, less marked in the aorta; venous blood bright red, as in coal-gas poisoning. There was no ecchymosis in pericardium or pleura. No œdema and the absence of ecchymosis speak against asphyxia as the cause of death. It was intended to give chloroform to this patient, and perhaps the same fatality might have resulted. Thus the *pium desiderium* of a narcotic without a possible lethal effect cannot be looked for in this agent any more than in the others. Lotheisen then reports two additional deaths, one personally communicated by Soullier and another incidentally mentioned in passing, by J. Spengler, from Kocher's clinic. Both of these cases, because of their insufficient data and the uncertainty of the product used, ought to be excluded from the total statistics. If, then, this restriction be accepted, the death rate is 1 in 11,207 cases. Considering the early stage of its application, the showing for ethyl chloride is a very commendable and encouraging one.

Method of administration: A certain degree of concentration of ethyl chloride in the gaseous state is necessary, and whatever mask be used its walls must in greater part be impervious to air. It has been recommended to spray ethyl chloride upon the under surface of an ordinary chloroform mask covered with oil silk. To administer it thus is awkward, wasteful, and very uncertain, so I early abandoned this for the modified mouth-piece of the nitrous-oxide apparatus, the inspiratory valve of which is replaced by a piece of gauze guarded on its distal side by a wire net to prevent aspiration of the gauze. The orifice of the gas-supply tube is occluded, and the sliding tube being removed, the ethyl chloride is sprayed through the air vent on to the gauze. A couple of cubic centimetres are sprayed at a time, and the effects watched. In place of this special mask, equally reliable is a tin or vulcanite funnel, given by a little pressure a shape to conform to the features of the face, with a notch to correspond to the bridge of the nose. Into the neck of the funnel, a piece of gauze is inserted, and a window may be cut into the wall of the funnel to act as an outlet. An improvement in the technique greatly furthering the economic use of ethyl chloride, which I have latterly used, consists in imitating the drop method of chloroformization by spraying ethyl chloride intermittently with short remissions. By this procedure the frosted breath will not accumulate on the gauze, like hoar frost, in such quantities as to interfere with the inhalation of ethyl chloride.

Effects of the drug: The inhalation of atomized ethyl chloride is pleasant, having a sweet taste, akin to that of chloroform, unattended by any choking, and never by any salivation. The intense cold produced by evaporation of ethyl chloride is not perceptible on inhalation, as a personal trial will soon convince. Marked excitation is encountered only in alcoholics and highly neurotic patients, wherefore the latter should be spared all excitement. On an average, when 10 c.c. have been used, and this after an interval of one or two minutes, the requisite anæsthesia is attained. The breathing is perfectly natural, and, in the narcotic stage, becomes somewhat stertorous; at times the usual attention has to be given to the falling back of the tongue. The pulse becomes somewhat accelerated and remains so throughout, but digitally no fall in the pressure is appreciable. There is constantly a profuse flushing, notably of the face, followed by free perspiration. There are slight jactitations followed by spastic state of the muscles, which relax considerably in degree as the narcosis is pushed. The muscles of the chest are not thus affected, for never was any interruption in respiration encountered from this cause. Observers are at variance as to the pupillary reaction, but I think very early in the administration of ethyl chloride the pupils begin to dilate; this preliminary dilatation is followed soon by a moderate contraction, which again passes into dilatation if the anæsthetic is pushed too far. The narcotic stage is judged to have set in when the pupils are becoming smaller, when the muscular contractions abate, and when the breathing is slightly stertorous. The extreme volatility of ethyl chloride makes it impossible to rely on any one symptom, as all are fugacious, yet the evolution of the various stages is like that of other anæsthetics but so rapid that, after the expiration of one to two minutes, narcosis sets in abruptly.

On the authority of Ludwig and Lotheisen, I quote that it has been kept up for forty minutes. The longest period it was given by me was to a child aged fifteen months, for castration of tuberculous testis, during fifty minutes. Regardless of the duration of its administration, the awakening is short of being instantaneous, and unless food has been ingested immediately before narcosis no vomiting whatsoever ensues, and moreover there are no unpleasant after-effects to record. I have to report a single instance of alarming symptoms. In a child afflicted with extensive adenoids, not recognized prior to the operation—incision for cellulitis—asphyctic phenomena set in, yet with care the drug's use was continued, and again applied on a subsequent occasion calling for more incisions.

Departures from the above phenomena will be the rule in alcoholics, neurotics, and children. Alcoholics show marked excitation and require larger quantities, and, if at all narcotized, remain very rigid. To offset these bad effects, Lotheisen claims to have good results accrue from a preliminary use of a hypodermic injection of heroin, to which he also resorts when a long operation is expected. As to neurotics, a little explanation and the quietest of surroundings will greatly facilitate the anæsthesia. In children the anæsthesia is at its best, and they have been the most fertile source of my experience. With them how little irritating the vapor is, may be judged from the freedom of respiration, the absence of any struggle, rapid sleep, and almost always complete relaxation of the muscles. At all other ages the slight muscular rigidity present must be a deterrent factor from the use of this agent for the more delicate work of major operations. The rigidity is not marked enough to interfere with the reduction of fractures. No bad effects on the kidneys or lungs after long operations have been recorded.

Physiologically viewed, ethyl chloride seems to act selectively on the sympathetic nerve, judging from the accelerated pulse, flushing, and a transient dilatation of the pupil; next it seems to act on the spinal cord, and lastly on the brain, but on all of these in very rapid sequence.

Chemically, being derived from the second series of hydrocarbons, it is in the direct line of relative safety of alcohol and ether, both derivatives of this group; but according to Benjamin W. Richardson, an anæsthetic is dangerous in proportion to the chlorine it contains,

and herein may lurk a possible danger in ethyl chloride, since it contains one molecule of chlorine.

With all of these pros and cons I hope, however, to have made out more than a fair case for ethyl chloride, and I would champion its use pre-eminently in minor surgery for the following reasons: It is as safe statistically as any of the others; it induces a very rapid narcosis and equally as quick an awakening, and is void of any after-effects. Against its chief competitor, nitrous oxide, be it said that it is cheaper, does away with any special apparatus, is portable, and its market is so wide-spread already as to place the drug at hand for the vast majority of physicians and surgeons.

Indications for its use arise in all minor work in which the exact limits of operative procedures can be predetermined. It has proved efficient for curettage and obstetrical anæsthesia (P. Mathes), expression of trachoma, reduction of fractures, and as a preliminary to narcosis with other agents. In the latter direction the experiences of Dr. J. P. Tuttle amply testify. Likewise, the beneficent effect of the mixture employed by Dr. Willy Meyer is in no small measure due to the ethyl chloride it contains. I am mindful of the fate of other anæsthetics, methylene bichloride and pental, whose use was very ephemeral, because of their great death rate right at the start; but this cannot be charged to ethyl chloride; therefore I think its future is secure, dependent largely on the liberal trial given it to ascertain its benefits as well as its limitations.

In conclusion, I wish to thank Drs. H. Streiffer and Dr. Celler, whose valuable assistance rendered possible the experiences herein narrated.

ON THE DIAGNOSIS AND PROGNOSIS OF DIABETES MELLITUS.[1]

By HENRY S. STARK, A.M., M.D.,
NEW YORK.

It seems to be very generally assumed on the authority of the most enlightened medical minds that the diagnosis of this dread affection resolves itself, first, in the detection of glucose in the urine, and secondly, in the proper interpretation of certain deviations from the lines of good health. Unless these prerequisites are satisfied we are not on safe ground in making a diagnosis. While in most instances the diagnosis is readily made when the disease has reached an advanced stage, still there is a large percentage of cases which furnish little or no clinical data, and which are consequently not easy of recognition, unless the clinician be a keen observer and a good urinologist. Among the cases likely to escape detection are those in which the urine is of low specific gravity, or those in which the urine shows only a trace of glucose, or those in which other urinary constituents than glucose, such as glycuronic acid, indican, or creatinin, reduce the copper or the bismuth of the test solutions, or lastly, those cases in which, for reasons unknown, the sugar in the urine fails to reduce cupric oxide at all.

[1] Read before the section on general medicine, New York Academy of Medicine, March 19, 1901.

The first consideration then in diabetes is to establish the existence of the disease; this, in view of its unascertained pathology, is not so easy as would at first appear; for I know of no disease in which it is so difficult to determine where physiology ceases and where pathology begins. Neither acute nor chronic glycosuria *per se* is sufficient evidence to warrant a diagnosis; for we know that both forms may occur under conditions which are compatible with the enjoyment of good health. Thus we may find a glycosuria of a transient character following an overindulgence in carbohydrates, or as a sequence of muscular fatigue, or following an anæsthesia by ether or chloroform, or following the ingestion of certain drugs, or following shock or a trauma, or accompanying a lesion of the brain or of the spinal cord. And yet not one of these conditions could be pathologically labelled as diabetes. We are thus confronted at the outset with the inquiry, When can a person be said to be suffering from diabetes? The answer is, Only when there is a glycosuria —persistent, transitory, or recurrent—accompanied by one or more of the classical clinical features of this disease, such as a polydipsia, polyuria, either or both accompanied by a general deterioration of health; in other words, there must be a characteristic syndrome, plus glycosuria, as determined by several interval analyses of a twenty-four-hours' specimen of urine.

While I do not purpose to recapitulate in chronological order all the symptoms of the disease in question, I wish, however, to allude to certain signs and symptoms which are not usually mentioned as such in the more familiar text-books, and whose presence singly or in combination ought always to arouse suspicion of diabetes. Among these evidences of the affection the following are the more prominent: Periodic attacks of headache in obese subjects over thirty-five years of age, extreme and lasting fatigue after a short but violent exercise, and prolonged fatigue, say, of one or two days' duration following a slight exertion; slowly failing vision in the aged or quickly failing vision in the young, certain signs referable to the mouth, such as acid saliva, receding gums, fissured and extremely reddened tongue. This is a combination frequently encountered in middle-aged women. Two varieties of symptoms are referable to the heart and its functions—the one set simulating an attack of angina pectoris and a second set presenting the physical signs of arteriosclerosis, or of cardiac hypertrophy. This latter set of cases may be met with not infrequently in obese male subjects with florid countenances and with otherwise healthy appearances. Another train of symptoms is referable to the nervous system. There are present marked nervousness and psychical disturbances; the patient is usually an old man of an ungovernable temper, is easily irritated, and, besides, is impatient; has a morose expression and lacks cheerfulness. Still other symptoms, which should put the clinician on his guard, are premature grayness, premature sexual weakness, diminished patellar reflex, slow healing of wounds, cramps in the calves of the legs in the morning hours, accompanied by muscular weariness.

While on the question of diagnosis, I wish to allude to certain vagaries, or rather anomalous types, of the disease. There are two which present such unusual features that they may be justly styled unique. In the first set the diabetic dyscrasia is present, but glucose cannot be demonstrated in the urine. In the second set, glucose can be demonstrated in the urine at intervals, during which times the subject presents no clinical manifestations of the disease. These masked or suspicious types have been described by Külz, von Noorden, Naunyn, and others. In an article on the treatment of diabetes, read by me before this section in 1897, I alluded to this first set of cases, styling it

"a glycosuric diabetes." That they are types of the diabetic diathesis is not beyond the pale of belief. At that time I instanced a special case. In addition to this latter, I have several other parallel cases under observation. These patients merely possess to an unusual degree the power of assimilating carbohydrates; that is, their metabolic function for amylaceous food is plus the normal, so that sugars and starches are burnt up in their systems without giving rise to a glycosuria. This tolerance, as it were, for carbohydrates varies within wide limits in different individuals, and in the same individual under different conditions. Fortunately we have at our command, as von Noorden, Külz, and Pavy have shown, a method of ascertaining and, to some extent even of controlling, this tolerance for carbohydrates. These investigators made use of the so-called "carbohydrate test meal" to ascertain the degree and power of an individual to assimilate amylaceous food. Such a standard meal consists either of a known quantity of glucose itself, or of a specified amount of an article of diet rich in carbohydrates, as wheaten bread. The one or the other is administered in addition to a breakfast of proteid and fatty food. If no glucose appear in the urine of the next twenty-four hours, the quantity of glucose or starchy food, as the case may be, is proportionately increased the next morning, and another examination of the urine is made twenty-four hours after the test meal. This daily procedure continues until glucose can be demonstrated in the urine, when it is measured and compared with the amount of ingested carbohydrates, thus establishing the ability of the individual to assimilate carbohydrates, with almost scientific accuracy. This test meal, the details of which may be found described in the monographs of Külz or von Noorden, furnishes an excellent clew to establish a diagnosis of diabetes in certain doubtful or mild cases in which there is no palpable deviation from health.

As an aid to diagnosis, the science of bacteriology has been practically a dead letter. Although bacteria have held the centre of the stage during the last years of the past century, yet in diabetes they seem to have made no inroads. What a lucrative field for the bacteriological enthusiast to invade! True, there have been recorded a number of cases of bacterial origin, yet in no instance did the reporter submit satisfactory bacteriological proof to sustain his claim.

Nor have examinations of the blood, chemical or microscopical, been productive of the happiest results. Still, the blood-staining methods of Bremer and of Williamson give promise of great value; but these are still in an experimental stage. Bremer claims that by his method of staining diabetic blood a diagnosis can be made before glucose appears in the urine, and even after it has temporarily disappeared; whereas Williamson has found positive results in eleven cases of diabetes and negative results in one hundred cases of diseases other than diabetes. Bremer's test consists in heating to 135° C. a drop of the patient's blood upon a glass slide. A one-per-cent. Congo-red solution stains diabetic blood red permanently, but the color may be washed off from a control specimen of normal blood.

Williamson says that a drop of diabetic blood decolorizes a warm alkaline solution of methylene blue, when mixed in certain proportions, to a yellowish-green or yellow. This action he claims to be due to glucose. These blood tests are available for diagnostic purposes in post-mortem cases, and are, therefore, valuable in a medico-legal aspect.

The crucial diagnostic factor in diabetes is glycosuria. For the detection of sugar in the urine we have tests which are bewildering in their variety, and this very fact is the best evidence that most of them fall short of being absolutely reliable. Thus we have biological or fermentation tests; the optical or polariscope test; the gravimetrical tests, by reduction of an alkaline copper or bismuth solution; the volumetrical tests, by reduction of copper or mercury solution; the microscopical test of phenylhydrazin crystals. Each of these classes of tests depends upon a different property of grape sugar, and has a certain face value which depends upon whether the test is made for clinical purposes or for experimental purposes in a laboratory. Many of them are so theoretical in their application that they find no place outside of scientific books. Of all the carbohydrates, glucose is probably the only one of clinical interest; the others—lactose, maltose, dextrin, and levulose—occur in the urine under physiological conditions in such small amounts that their presence can be ignored. While each of these classes of tests possesses certain advantages over the others, there is no class free from sources of error, so that to-day we have no absolutely infallible test, the nearest approach to the ideal being the fermentation, for the reason that glucose is practically the only fermentable substance that pathological urine contains, and secondly, for the reason that the only constant and characteristic reaction of glucose is its property of fermentation in the presence of yeast and its conversion into alcohol and carbon dioxide.

The yeast-fermentation test, therefore, especially the differential-density test of Roberts, is one of the most trustworthy for office work. For the relative quantitative determination of sugar, Fehling's test still holds its own. We must, however, in employing this test bear in mind certain imperfections. First, other substances than glucose may be present in urine and reduce the cupric oxide, and secondly, other urinary constituents may retard or mask the copper reduction. Among the substances which may reduce copper and may thus be mistaken for sugar are the following: (*a*) Glycuronic acid; this constitutes the chief source of the pseudo-reaction; (*b*) certain drugs of the aromatic series, the fatty series, the coal-tar preparations, the alkaloids—examples are creosote, guaiacol carbonate, eucalyptol, cubebs, copaiba, tannin, chloral hydrate, salicylates, and sulphonal; (*c*) other urinary ingredients, as alkapton, indican, creatinin, nucleo-albumin, uric acid, and urates. Of substances which retard the reduction or mask it are albumin in excess, peptones, propeptones, and ammonia salts. The effects of these interfering agents may be minimized by chemical measures, such as free dilutions with water of the suspected fluid, or subjecting it once or twice to animal-charcoal filtration, which readily extracts uric acid, urates, creatinin, and coloring-matters. Another means of obviating these errors is to submit the suspected fluid to control tests, and this is the secret of success in determining the presence of sugar in urine; that is to say, not any test should be considered decisive unless supplemented with positive results by another variety.

The reduction tests by copper and by bismuth have then a certain negative value, by which I mean that it can be assumed that urine which does not reduce these solutions is free from sugar, but, conversely, reduction does not conclusively establish its presence. All the tests differ in sensitiveness and reliability, and it does not follow that the most sensitive is the most reliable; for instance, Trommer's copper test is more sensitive than most other tests, but it is by no means as reliable, inasmuch as it fails to detect glucose in amounts less than 0.5 per cent. Again, the phenylhydrazin test, one of the most sensitive, is incidentally one of the most unreliable. The real merit of any test, from a practical and a clinical standpoint, depends upon the ease with which it can be accomplished, the time involved in its accomplishment, and its relative reliability and delicacy. It is one thing to examine urine for

sugar in the office, and quite another to do so in a chemical laboratory. In the former we look for practical results; in the latter for percentages. Taking all conditions into consideration, and with a knowledge of most of the methods and of the instruments of precision in vogue for the quantitative detection of glucose in urine, I cannot help thinking that, for all intents and purposes, one of the quickest, most delicate, and most certain methods is that devised and perfected by Dr. J. Rudisch, of New York. It can be employed in the office, and his double-titration method, which involves only one-half to one hour in its operation, detects even such small amounts of sugar as 0.1 per cent. The single titration, with his test solution into diluted urine, is, according to his statement, "accurate enough for all purposes required by the physician, and can be done more quickly than by any other method."

My limited experience with Rudisch's saccharometer has convinced me that his claims are not exaggerated. The test solution is made up as follows: Copper sulphate (crystallized), 4.78 gm.; sodium sulphite, 50 gm.; sodium carbonate (crystallized), 80 gm. Dissolve in 10 per cent. ammonia water and make up to 500 c.c. One c.c. is decolorized by 1 milligram of sugar.

Prognosis.—In considering this aspect of the disease, it is always the part of wisdom to be reticent in our opinions regarding the intrinsic tendencies of an individual case, inasmuch as a correct judgment of its termination and course cannot be formed until the patient has been under observation for some time, this being especially true in the beginning stages of the disease. In general terms it may be claimed that the majority of cases are amenable to treatment. There are cases presenting numerous and aggravated symptoms which run a favorable course under treatment, while there are other cases with few and mild symptoms which run a protracted course, the cases varying within these two extremes within wide limits. There are those who believe that a permanent cure can be hoped for in some mild cases; there are others who believe that once the disease is established beyond peradventure complete recovery never follows. One fact, however, is well established, that under proper *régime* and diet in a majority of cases patients may live for years—three to fifteen—during most of which time few subjective symptoms may present themselves.

Of great prognostic importance are the following features: (*a*) Age, (*b*) power of assimilation of carbohydrates, (*c*) early recognition of the affection, (*d*) the presence of intercurrent and complicating diseases, (*e*) condition in life, (*f*) state of the urine, (*g*) the power of absorption of other foodstuffs than carbohydrates.

(*a*) Age: In those rare instances in which the disease occurs in childhood it has rapidly proven fatal. This is the only disease in our nosology in which old age is an advantage. The severe forms are better borne in advanced age than the mild forms in youth.

(*b*) Power of assimilation of carbohydrates: This tolerance is ascertained by a quantitative determination of glucose; urine containing one-half per cent. to two per cent. is regarded as belonging to the mild type. One containing five per cent. to ten per cent. is viewed as belonging to the severe type. Decided improvement can be expected when the system is capable of disposing of 200 grams of carbohydrates daily without giving rise to a glycosuria. Permanent intolerance for carbohydrates is an unfavorable prognostic indication, and those cases offer the most unfavorable prognosis in which a glycosuria persists despite the most rigid antidiabetic diet, the glucose being ultimately derived from the metabolism of proteids and from the tissues.

(*c*) The early recognition of the affection has an important prognostic bearing. The sooner the disease is recognized the greater the possibility to maintain nutrition, and the more hopeful will be the subsequent course of the disease.

Right here I wish to offer a plea for the advisability of instructing the laity regarding the necessity of systematic examinations of the urine, even when in the enjoyment of apparent health. I believe much misery and suffering could be averted if all persons over thirty-five years of age would make it a routine practice of their life to have a chemical analysis of their urine made, say, twice in each year, just as they submit their teeth to the regular inspection of their dentist. With this precaution, time and again, the incipient stages of more diseases than diabetes could be detected and disaster averted.

(*d*) The presence of complications or of intercurrent diseases offers a serious drawback in the course and termination. Pulmonary tuberculosis and coma are frequently the cause of death, while syphilis, obesity, and gout are rather favorable prognostic components.

In several cases of uterine cancer complicating diabetes, I have seen the glucose disappear months before death; in certain other diseases, such as nephritis, the same phenomenon obtains. In influenza accompanying diabetes, the sugar does not usually disappear. In gouty and in corpulent individuals the diabetic condition may be markedly ameliorated, but in thin and nervous subjects the ultimate prognosis is unfavorable. The cutaneous manifestations are unfavorable indications.

(*e*) Condition in life: Patients who can afford to lead a sedentary life, free from care and worry, devoting their time and means to an alleviation of their condition, usually succeed in warding off many of the disturbing elements of the disease and in prolonging life. On the contrary, patients who are forced to engage in exacting manual labor, or in prolonged and exhausting mental work, become easily the prey to the ravages of the disease.

(*f*) State of the urine: In addition to glucose, the urine may contain other threatening evidences of the diabetic dyscrasia. Thus we may find excessive amounts of acetone, diacetic and β-oxybutyric acids. The presence of the first of these urinary elements in large quantities, and of the second and third in appreciable quantities, is of grave importance as portending the approach of coma. If it be true that diabetic coma is due to a hyperacidity of the blood—a sort of acid intoxication—we can then readily understand how important it is from a prognostic standpoint to cause a rapid elimination of these organic acids. Acetone occurs physiologically in urine in insignificant quantities; if it accumulate in comparatively large quantities, the severity of the disease is in direct proportion to the amount. Diacetic and β-oxybutyric acids never occur in urine in physiological conditions. The quantity of urea eliminated is also of great prognostic moment, as it supplies the best clew regarding the rapidity of tissue destruction or of retrograde metamorphosis of the nitrogenous foods. If a proteid equilibrium can be maintained, so much more favorable is the ultimate course of the disease. The relation between the ingested proteids and the urea eliminated, while in no instance a fixed quantity, nevertheless operates in accordance with the fixed laws of metabolism. With a knowledge of the rate of urea elimination, the physician can direct the patient regarding the quantity and quality of his food.

(*g*) Finally, the prognosis depends upon the capacity of the system to absorb and assimilate fatty and nitrogenous food, to the exclusion of carbohydrates. If nutrition and the metabolic functions can be maintained under a strict diet, the patient will hold out a

long time; if, however, glucose continue to be formed despite the rigid exclusion of carbohydrates—that is, from the proteid food, from the fats, and from the tissues themselves—the aspect of the case becomes serious.

From what has preceded, it is evident that all cases arrange themselves in one of three types from a prognostic standpoint. First, the mild type; secondly, the medium type, and thirdly, the severe type. To the mild type belong those cases in which the glucose disappears upon the gradual exclusion of carbohydrates. To the medium type belong those cases in which the glucose disappears only after the complete exclusion of carbo-hydrates. To the severe type belong those cases in which the glucose does not disappear despite the complete exclusion of carbohydrates and even of proteids.

156 East Seventy-second Street.

Fifty-eight Cases of Puerperal Eclampsia without Mortality.—W. Stroganoff, in summing up the leading principles which he believes should guide the physician in the treatment of eclampsia, states the following: 1. After the first attack narcotics are to be used prophylactically for a varying period. 2. The combined use of morphine and chloral seems to have the best effect. 3. It is desirable to discontinue the narcosis in from twenty-four to forty-eight hours, according to the intensity of the attack. 4. The most careful attention should be paid to securing the following result, viz., that the lungs and heart perform their functions regularly and actively; for the latter purpose it is especially important that liquids be given per rectum, or if the patient be unconscious, by the mouth. 5. All sources of irritation should be removed. 6. Delivery should be accomplished as rapidly as is possible without danger. The writer has had in fifty-eight cases 0 per cent. mortality from eclampsia and 1.7 per cent. from complications. No less favorable is the result as regards the children.—*Obstetrics*, February, 1901.

The Sensitiveness of the Abdominal Cavity, and Local Anæsthesia in Hernia Operations and Laparotomies.—K. G. Lennander believes that the pain in abdominal operations, colic, peritonitis, etc., originates solely in the parietal peritoneum, and that the other abdominal contents are devoid of sensory nerves. By actual experiment during an extended series of herniotomies and laparotomies done under local anæsthesia he was able to satisfy himself that the stomach, intestine, mesentery, kidney, gall bladder, and liver may be handled, incised, or cauterized without causing the patient any sensation whatever, while any manipulation involving the parietal peritoneum is sure to be accompanied by acute pain. It is especially stretching of the membrane that gives rise to pain, and the application of retractors or the walling off of the operative field by the insertion of gauze compresses is acutely painful. In view of these observations, he concludes that the pain of peritonitis begins only when the parietal peritoneum commences to be inflamed; so that cases in which the disease is restricted to an inner localized area should run a painless course, a supposition that is borne out by clinical experience. The pain of intestinal colic also depends not on the actual distention of the gut itself, but on the acute traction exerted on the parietal peritoneum, while in ascites, for example, the process takes place so slowly that no discomfort is caused. In cases not permitting protracted anæsthesia to the full degree, it is recommended to begin the operation under light morphine-ether narcosis, and to prepare the field for whatever internal manipulation may be necessary, during the carrying out of which the administration of the anæsthetic may be omitted, to be resumed again when the pads are to be removed and the sutures inserted.—*Centralblatt für Chirurgie*, February 23, 1901.

Splenic Anæmia as a Morbid Entity.—Tommaso Guida holds that it is a misnomer to call the complex of symptoms known as splenic anæmia a disease. It is a syndrome, which often prepares the way for diseases, more especially tuberculosis. It is due to malnutrition, or more exactly, to malassimilation. The physician should endeavor to ascertain the cause of the condition, and to remedy the defects in diet. In cases of hereditary syphilis, specific treatment will, of course, be administered. Splenic anæmia is on the decrease, owing to the wider dissemination of hygienic and alimentary knowledge.—*La Riforma Medica*, January 29, 31, and February 1, 1901.

Meningitis, Secondary to Croupous Pneumonia.—Giuseppe Pollaci says that the presence of one or of a very few symptoms is not sufficient for the diagnosis of a meningitis complicating pneumonia; but when all the characteristic symptoms are present (increased temperature, retention of urine, rigidity of the back of the neck, headache, delirium, venous stasis of the retina, etc.), we may be sure of our diagnosis. A few isolated symptoms, with negative symptoms of the fundus of the eye, might be caused by an inflammatory condition of the cerebral membranes, it is true; but might with equal justice be attributed to functional lesions of the nerve centres, produced by the toxic elements arising from the pneumonic process.—*La Riforma Medica*, February 16, 18, and 20, 1901.

Errors of Diagnosis and of Treatment in the Diseases of Women.—L. Berruti calls attention to various errors made in gynæcological practice, which lead to harmful results. Among these are local treatment for amenorrhœa or metrorrhagia, due to chlor-anæmia, approaching menopause, or some disease of the circulatory or respiratory organs; or the opposite mistake of instituting general treatment for causes which careful examination would have shown to be purely local. Many cases of dysmenorrhœa and sterility are dismissed as unavoidable, when dilatation of the cervix, the breaking down of adhesions, or internal uterine treatment might bring relief. Many cases of inflammation remain undiscovered until too late. A mania for gynæcological examination and treatment on the part of non-specialists often results in the aggravation of existing conditions, while uterine catarrh, tumors, displacements, etc., frequently result from neglect.—*Gazzetta Medica Lombarda*, February 10, 1901.

The Diazo Reaction as a Test for Bilirubin.—F. Pröscher describes a color reaction for bilirubin which is said to be very delicate. If the diazo solution be added to a solution of bilirubin previously acidified with nitric acid, a beautiful blue color is produced; if the reaction be made alkaline, the color changes to green, while neutral solutions of azo-bilirubin give a splendid red color. In this form the reaction, however, is not adapted for use in testing icteric urine, for this appears to contain some substance not present in normal specimens, which interferes with the color formation and gives muddy or yellowish mixtures instead of the characteristic shades. For practical use the following technique is recommended as giving reliable results: A small amount of urine is saturated with ammonium sulphate and the resulting colored precipitate filtered out through a small paper filter. This is now washed with ninety-six-per-cent. alcohol and the resulting solution acidified with nitric acid and then added to the diazo reagent.

The presence of bilirubin is indicated by the production of a deep blue color, which changes to red and green, as above described, on the cautious addition of sodium hydrate.—*Centralblatt für innere Medicin.* February 16, 1901.

Operation for Appendicitis.—Jose A. Presno summarizes his article as follows: (1) The frequency of epiploic lesions in cases of chronic appendicitis—lesions to which the post-operative pains of appendectomy may be ascribed. (2) The necessity for excising all inflamed and adherent portions of the epiploon. (3) The necessity for a careful examination of the epiploon in every case of laparotomy.—*Medical Press and Circular*, February 6, 1901.

Allotropic Iodine.—G. Levi has produced allotropic iodine from the metalloid, which differs radically from the latter physically and chemically. It is very diffusible as regards the tissues and the mucous membranes, being rapidly absorbed, without leaving any trace when injected hypodermically. It renders the serum of a horse bactericidal toward the bacillus pyocyaneus. Experiments with this serum upon guinea-pigs, which had been inoculated with tuberculosis, showed that, although the animals died and tubercles were found in the liver, spleen, etc., as in the case of non-immunized animals, yet the lungs showed no sign of disease.—*La Riforma Medica*, February 20, 1901.

Regeneration of the Suprarenal Capsules.—G. B. Ramoino concludes from experimentation that after cutting, crushing, and cauterization of the capsule, there occurs extravasation of blood, more or less extensive mortification of the parenchyma, followed by inflammatory reaction and reparation by means of cicatricial tissue. Hemorrhage was greatest when a section was cut out with the knife, and least when caustics were applied. Necrosis was least when the knife was used. Small-celled infiltration was most abundant after crushing or cauterization. Wounds that extend into the medullary tissue are followed by greater hemorrhage, more intense inflammatory reaction, and more abundant formation of cicatricial tissue than when the cortical substance only is injured.—*La Riforma Medica*, February 2 and 4, 1901.

The Value of Continuous Catheterization in Some Genito-Urinary Affections.—H. M. Christian says that in the employment of continuous catheterization, one important point in the technique must not be overlooked, and that is to see that no part of the catheter is allowed to remain in the bladder itself. The instrument should be very slowly introduced and should be retained permanently at that point at which the first urine begins to flow, the object of this manœuvre being to keep the eye of the catheter in the prostatic urethra. Any portion of the instrument remaining for any length of time in the bladder is bound to provoke congestion of the trigonum, hæmaturia, and vesical tenesmus, conditions which will not only add considerably to the patient's suffering, but will materially add to the dangers of bladder infection.—*Therapeutic Gazette*, February 15, 1901.

A Case of Hysterical Deafness.—F. Schultze reports a somewhat unusual case of hysteria, in which almost the only symptom was absolute deafness affecting both ears. The patient was a boy aged fourteen years, of good family history, who had never been ill and was free from any neurotic tendency. While locking a desk he was suddenly startled by the banging of a door, so that he dropped the key he was holding and was found to be totally deaf. No local lesion could be diagnosed, the reflexes, including that of the pharynx, were normal, and no reason for simulation could be found. For a time the treatment consisted in electricity and hydrotherapy, when hysterical convulsions, at first of the arms and shoulders, later of the entire body, developed. These ceased spontaneously after a few days, but the deafness continued unabated until one day after removal to the hospital the hearing returned as suddenly as it had disappeared six weeks previously.—*Deutsche Aerzte-Zeitung*, February 15, 1901.

A Handy Device in Opium Narcosis.—In order to keep a patient awake during opium narcosis, W. H. Lyne advises a thorough tickling of his body, which procedure, he says, not only awakens the patient but angers him nearly to the point of fighting. He summarizes the advantages of this method by saying that the doctor has it handy, it has a wide range of application, is simple, leaves no marks of violence, and is efficient.—*Virginia Medical Semi-Monthly*, February 22, 1901.

Should Fever be Treated?—M. Lépine concludes that in certain diseases hyperpyrexia, while indicating the gravity of the febrile condition, is not the most important factor, and we must endeavor to find a specific treatment for the fever. In others we are reduced to constant supervision of the organic reaction, sometimes moderating it by means of antipyretics, sometimes stimulating it by means of hydrotherapy, and occasionally, if very high, by direct antipyresis, and, lastly, by sustaining the economy. Disease is by no means a simple entity, and therapeusis has for its object to follow up the infinite complexity of its elements.—*Medical Press and Circular*, February 27, 1901.

The Amelioration of Paralysis Agitans and Other Forms of Tremor by Systematic Exercises.—John Madison Taylor is convinced that in most forms of tremor, whatsoever their cause, we may hope to obtain fair amelioration of symptoms, and it may be in some instances a cure, by carefully regulated and systematized movements. These should be such as shall reestablish the largest degree of elasticity in the tissues which have suffered contractures. They should always include passive extensions and flexions, followed by active repetitions of these acts. The most important movements to overcome the milder forms of tremor, as the senile form, are slow, full, forcible extensions. An important part of this treatment is the attainment of normal attitudes. Along with this should be continued conscientious efforts on the part of the patient to acquire full thoracic capacity and as much elasticity of the lungs as possible. To regain and maintain health and activity in chronic conditions of almost any sort, is conditional upon a fair respiratory capacity constantly exercised.—*The Journal of Nervous and Mental Disease*, March, 1901.

The Psychology of Profanity.—G. T. W. Patrick has made a study of the psychology of profanity, in which he asks and endeavors to answer two questions: 1st, why do men swear, and 2d, why do they use the words they do? Profanity is defined as "the ejaculatory or exclamatory use of a word or phrase, usually the name of the deity or connected in some way with religion or other sacred things, having no logical connection with the subject in hand, and indicative of strong feeling, such as anger or disapproval." As regards the subjective effects of profanity, the most striking is that of a pleasant feeling of relief from a painful stress. Some words seem made for special circumstances. "Even men who do not swear can by a sort of inherited instinct appreciate the teleological relation exising between the behavior of a refractory collar button during the hurried moments of dressing for some evening function and the half-smothered

ejaculation of the monosyllable 'damn.' The word seems to have been made for the occasion." In a general way it may be said that the author regards profanity as a reversion to a type of expression comparatively low down in the scale of development of language. The human oath is the analogue of the roar or growl of anger of the lower animals.—*Psychological Review*, March, 1901.

Temperatures of Healthy Children.—W. M. Donald states that he has noticed in institutional work that when healthy children were isolated and quarantined on account of suspected exposure to some contagious disease, the temperature by accurate thermometric tests showed marked variations. These variations seemed to be due partly to individual peculiarities of temperament and partly to variations in atmospheric temperature. A series of tests was undertaken, some twenty children being selected who were in perfect health. The temperature of each was taken twice daily, at about 8:30 A.M. and 6 P.M., for a period of fourteen days. During the fourteen days in which the tests were conducted, there were, of course, 28 collective readings, and out of the 28, 12 readings, or 42 per cent., gave a mean or average temperature of 99° F. or over. As was to be expected, the higher readings occurred at the afternoon tests in the majority of cases; 9 of these being recorded in the afternoon, and but 3 in the morning aggregate. On 5 different occasions, or about 18 per cent., the mean temperature on the collective reading showed a higher range in the morning than in the evening of the same day. This is contrary to the usually accepted dictum that the normal evening temperature is always higher than that of the morning, and was a point of considerable interest. Leaving now the collective and taking up the individual readings, it may be premised that there were in the aggregate 560 temperature records. Out of these 560 records, 13, or .02 per cent., showed 100° F. or over. On one occasion a child was found with a temperature of 101° F., and once a temperature of 102° F. was discovered in another child. The minimum readings showed 13 out of 560 records, or .02 per cent., to be under 98° F. As a matter of fact, they were usually 97° F. or 97.4° F. In the course of his tests, Dr. Wilson, upon a single occasion, found a temperature of 96.4° F. Another point which is of marked interest, and which was manifested in about 30 per cent. of the cases examined, was a tendency toward a constant high temperature.—*Archives of Pediatrics*, March, 1901.

The Treatment of Hemorrhoids by Elevation of the Pelvis.—G. Oeder describes a simple method of treatment which in his hands has given great relief and often made surgical intervention unnecessary. Starting with the idea that the hemorrhoidal varicosities depend on the weight of the blood column which has to be forced upward the whole distance from the anus to the heart before any valves are encountered, by placing the starting-point higher than the destination he allows the stream to flow by gravity away from the congested area and quickly relieves the painful distention. This is best effected by placing across the centre of the bed, one on top of the other, two ordinary wedge-shaped bolsters, the thin end of the wedge being toward the head. Under the weight of the body these become depressed, so that the pelvis is actually about ten inches higher than the heart and the body is prevented from slipping down the incline by placing the bolsters at such a point that when the patient is recumbent his head will just impinge against the head of the bed. Suitable pillows may be placed under the head, the only object being to keep the pelvis higher than the heart, and the patient readily finds comfortable attitudes on his back or semi-prone. Whenever the customary premonitory symptoms of a fresh access of the trouble are felt it usually suffices to sleep one or two nights in this position, and even obstinate cases are often cured by its habitual employment for a longer period of time.—*Zeitschrift für diätetische und physikalische Therapie*, vol. iv., No. 8, 1901.

Miliary Tuberculosis, Tuberculous Meningitis, or Typhoid Infection ?—Colla Vittorio reports a case in which the symptoms pointed with apparent clearness to a diagnosis of general tuberculosis with involvement of the meninges. A bacteriological examination of the fæces however, gave evidence of Eberth's bacillus in great numbers, while examination of fluid obtained by lumbar puncture was negative as to Koch's bacillus. The autopsy bore out the diagnosis of typhoid infection. —*La Riforma Medica*, February 26 and 27, 1901.

Injection According to Bier's Method in Sciatica.—Felice. Pullé reports the case of a man suffering from sciatica. Other methods of relief having failed, the author gave an injection of a two-per-cent. solution of cocaine in the spinal cord at about the fourth lumbar vertebra. Just before the injection the patient's temperature was 37° C.; pulse, 70; respiration, 18. Ten minutes after the puncture the temperature was 37° C.; pulse, 74; respiration, 24. Analgesia was complete. Some general symptoms such as headache and anorexia followed, but these soon disappeared, and on the fourteenth day the patient was dismissed, cured, from the hospital.—*La Riforma Medica*, February 22, 1901.

Exophthalmic Goitre Successfully Treated with Collodion Dressings.—The collodion is spread over the skin of the affected area and by the evaporation of the ether there is set up a compression of the goitre which leads, by largely cutting off its blood supply, to a reduction of its size and a diminution of its secretive function. This plan has been successfully followed by A. T. Haight who gives the following directions for its employment: 1. The collodion must be absolutely fresh, so that the maximum degree of contraction will be obtained at each application. 2. Rapid evaporation will be secured by using from twenty to thirty pounds of air pressure, thereby increasing the compression fully one-third. 3. The patient's head should be placed in an easy position, with muscles relaxed. 4. The collodion may be applied with a brush or cotton carrier and the pressure should be kept constant by repeated applications, as required, at intervals of from two to five days.—*Chicago Medical Recorder*, March, 1901.

Wheeling for Health and Not for Records.—From an extensive experience in noting the effect of bicycle riding on candidates for life insurance, F. S. Grant gives the following directions: 1. Do not ride a wheel before getting a medical opinion as to your physical condition and fitness. 2. Learn to ride properly and thoroughly to control your wheel before taking to the road. 3. See that your wheel is equipped with some form of reliable brake. Abandon high gears. 4. Learn to use, not abuse, this wonderful invention and graceful means of locomotion. 5. Never exceed your strength—ride for health and recreation, never for records. 6. Ride regularly, time and weather permitting, regardless of seasons. 7. Change your clothing immediately after coming from a ride. Take a tepid bath with ammonia added and sponge off with cool water and good rub. Put on dry underwear. 8. Finally, be considerate and thoughtful of man and beast, women and children and fellow-wheelers when out on the road. Strictly follow "the rules of the road," and compel others to do the same.—*Medical Examiner and Practitioner*, March, 1901.

MEDICAL RECORD:

New York, April 6, 1901.

CIRCUMCISION AS A PREVENTIVE OF VENEREAL DISEASE.

CRITICAL investigation will often disclose a useful purpose at the bottom of commonly observed practices. For instance, there are many religious customs that are based upon sound, sanitary doctrine. Thus certain dietetic regulations have been shown to be effective in the prevention of disease. So, too, it is held by many that the rite of circumcision is a salutary measure, tending to diminish the frequency of local disease, particularly of a venereal character. Ricord considered the prepuce an unnecessary and useless appendix, capable of acting as a source of much inconvenience, and predisposing to venereal infection. In a discussion of this question, E. Harding Freeland (*Lancet*, Dec. 29, 1900, p. 1869) is sanguine enough to believe that "if it were possible to secure the efficient circumcision of every male in infancy, not only would many of the disorders incidental to the genito-urinary organs in childhood, adolescence, and adult life be prevented, but also—a fact of far greater importance—that the incidence of that scourge of humanity, syphilis, which, in its ever-varying phases, permeates all classes of society, at every period of life, would be materially diminished."

Concerning the operation itself, it can be regarded as perfectly safe in the hands of a competent surgeon employing modern aseptic methods. In the next place the removal of the prepuce in no way interferes with the physical well-being of the individual. There is no evidence that the operation diminishes sensuality or procreative power. The justification for its performance resides in the fact that it is a most important factor in the prevention, not only of such conditions as dysuria, enuresis, retention of urine, balanitis, constriction of the glans, hernia, prolapse of the rectum, difficulty in sexual intercourse, aggravation of gonorrhœa, a liability to contract evil habits, together with a host of nervous symptoms, but also of syphilis.

The operation of circumcision results in the removal of the various pocket-like folds that exist around the glans and favor retention of secretion; and thereby the risks of irritation and excoriation, as well as the implantation of disease germs, are reduced to a minimum. The dry and somewhat thickened condition of the epithelium of the glans following circumcision offers an additional barrier to any local infection. Statistics show that the incidence of syphilis is far less among the circumcised than among the uncircumcised, although that of the other venereal diseases is greater, showing that the difference is due not to morality, but to the anatomical conditions present. It is the prepuce that, in the male, is the seat of election for the primary lesion of syphilis, so that if this structure were removed, a most prolific site for infection would be withdrawn, and, thereby, a most important source for the transmission of the disease would be destroyed. The effects of such removal would be appreciable with regard not alone to immoral and public women, but also to the wives of infected men. Evidence exists to show that syphilis is acquired less commonly by women from husbands who have been circumcised than from those who have not been, and that congenital syphilis is less common in the children of the former than in those of the latter.

For the operation of circumcision to be successful, toward the end of preventing syphilis, it is necessary not merely to remove the prepuce, but to effect, so far as possible, obliteration of all folds about the glans. Often too little of the structure is removed. The incision ordinarily should be made obliquely from above downward and forward, and slightly concave forward, so that when the skin retracts it may sit snugly behind the corona, the plane of the incision being as nearly as possible parallel to the plane of the corona. The reflected layer of the prepuce—the so-called mucous layer—which has been left untouched by this first incision, should, after being slit up and reverted, be carefully trimmed around the corona glandis, in such a way as to allow the cut edge to come neatly into contact with the cut edge of the part first removed. A wedge-shaped piece of frenum should always be excised. In this way the folds that exist on either side are obliterated, and the œdematous nodule that is apt to form at this point is prevented.

It is not likely that the practice of circumcision will ever become universal—any more than, for instance, preventive removal of the vermiform appendix—but the reasons that have been put forward should be sufficient not only to warrant its continuance when once the practice has been instituted, but to extend the field of its application. For those who see in it no religious justification, there is abundant reason of a less spiritual character for its performance; and the physician has placed at his command a potent means for restricting the ravages of a disease that he cannot hope ever entirely to eradicate, and which, while ordinarily amenable to treatment, is still capable of causing much suffering to innocent and guilty, to transgressor and victim alike.

A CURIOUS COMPARISON.

A POINT of perhaps negative utility, but at the same time of decided interest, is raised in the *National Provisioner* for March 9, 1901. The writer of an article in the journal named has been studying the health statistics of New York City, with the view of ascertaining whether the rich or poor sections of this metropolis are the most conducive to good health and long

life. The ordinary non-professional individuals and physicians as a body are firmly imbued with the belief that overcrowded districts are in the nature of things most inimical to sound health, and that poverty does not tend to develop a robust specimen of humanity. The remark should be made that the trend of the article in the *National Provisioner* is not toward proof, but rather intended to set forth facts.

Young children—that is those under five years of age—are first taken as a basis of comment. The figures given below are those cited for the second quarter of 1900. The Twelfth Ward uptown, where a fair sprinkling of the very rich of this city have their *pied à terre* and where their prosperous brethren have their more abiding homes, affords the following statistics with regard to the death rate of young children: This ward has a population of 364,412; has only 61.6 people to the acre, but its death rate for children under five years of age was 769, while the plebeian Thirteenth Ward downtown, in the vicinity of Grand, Division and Rivington Streets and the East River, with a population of 56,802 people and 539.5 to the acre, had a death rate of 106 children under five years of age. The relative percentages are in favor of the slums.

Other comparisons drawn between districts in which plutocrats live and those inhabited by the so-called lower classes bring to light a similar state of affairs. The total deaths of those of all ages in proportion to population is then dealt with, and reveals truths equally as suggestive. The Twelfth Ward in Harlem shows a total death rate of 2,287 for its 364,412 people, living 61.6 to the acre, while the Thirteenth downtown, with 56,802 people, living 539.5 to the acre, had a death roll of only 196.

The above figures give rise to thought. It is probable too that statistics taken in a like manner the civilized world over would yield somewhat corresponding results. No one of course would even attempt to argue from such records, that it is more healthy to live in a tenement house swarming with human beings like bees in a hive, than in an airy, well-ventilated, commodious, marble or brownstone structure. The writer in the *National Provisioner* does not argue thus; indeed, he draws but few deductions. Nevertheless he places his finger upon one important point when he says, "The poorer classes, eating plainer and more nutritious foods, seem to prosper constitutionally better than the eater of rich foods, who expects to digest his dinner by sucking in fresh air in a ride through the parks."

Moderation in eating and drinking, with plenty of fresh air and exercise, will go far toward rendering a person hardy and well able to withstand the attacks of disease. The contention would never be advanced by a sane individual that poverty and insanitary surroundings can have any but an injurious effect upon the human animal. On the contrary, the aim of the wisest sanitarians is to make it possible for every one to live amid healthful surroundings. Notwithstanding the obvious force of this statement the assertion may be made that, given a community of working people who are able to procure a sufficiency of wholesome food and who must perforce spend a large portion of their time exercising in the open air, and a community of rich people who are not compelled to lead such a life and who often do not do so, there can be no doubt as to which of these two classes will enjoy the longer life.

Many other causes enter into the question of the comparative healthfulness of the rich and the poorer classes. The fringe of the subject has only been touched in the foregoing remarks. To treat it fully from every standpoint would take reams of paper and much ink. It may be said that the rich can take lessons with advantage to themselves from their poorer neighbors so far as rules of health are concerned.

SURGICAL OPERATIONS ON THE INSANE.

Evidence of the complexity of the etiology of disease abounds on all sides. Even in the infectious diseases certain predisposing, auxiliary, or contributing influences are necessary for the pathogenetic operation of the specific exciting cause. This fact is deserving of consideration, and it is of significance both in prophylaxis and in treatment. For a time discussion waxed hot as to the part played by disease of the pelvic organs in the development of neurotic and psychotic states in women, and conservative minds have reached the conclusion that the former alone is not capable of inducing the latter, although it may contribute thereto, perhaps lighting into activity an already existing but latent tendency. The practical point, however, resides in the decision that pelvic disease should receive essentially the same treatment in neurotic or psychotic as in other women, the complicating state *per se* affording neither the indication for nor the counterindication against operative intervention, for instance—except in so far as every source of irritation or excitation or drain of etiological possibility should be removed. Of the value of such a course of procedure an illustration is afforded by the report recently made by Dr. W. C. Posey (Proceedings of the Philadelphia County Medical Society, vol. xxi., n. s. ii., No. 7, p. 251) of two cases of insanity in which mental recovery followed successful operation for cataract.

One of the patients was a farmer, forty-five years old, of temperate habits and with a good personal history, whose father had suffered from an attack of acute mania in the sequence of financial trouble, while a brother had been confined in a hospital for the insane as a result of sunstroke. Following an attack of "grippe," vision began to fail, and the patient at the same time commenced to be irritable, morose, and greatly depressed, with change in demeanor and the development of delusions of persecution. The opinion had been previously expressed that the cataracts present were not suitable for operation, but the removal of the riper of the two lenses was finally decided on, and was performed, on account of the objection of the patient, under general anæsthesia. The result was admirable with regard to both the success of the operation and the effect on the mental state. Correcting glasses were prescribed, and the patient was, after a little

while, permitted to return home on parole. Some time later the second eye was successfully operated on, at the request of the patient. The improvement persisted, and there had been no relapse after more than two years.

The second case occurred in a woman sixty years old, who had been depressed and melancholic for some time since her vision had commenced to fail. She consented to an examination only after considerable suasion, when it was found that both eyes were cataractous, the left in slight degree and the right in lesser degree. A correcting glass was prescribed for the right eye, and temporary improvement followed. After a time, however, it was decided to remove the cataractous lens of the left eye, and this was successfully accomplished under cocaine anæsthesia. The improvement in the mental condition was at once marked. Correcting glasses were prescribed six weeks later, and there was no return of the previous manifestations, although nearly three years had elapsed.

The cases are unfortunately rare in which such happy results as have been quoted can be brought about in the manner described. Such an outcome can, however, be hoped for only when the disordered mental state is due directly or indirectly to the visual defect; and operative intervention may be at once undertaken, although under other circumstances it might be deferred. If, on the other hand, the impairment of vision is but an incident in the course of the mental disorder, no such result can be anticipated, and under such circumstances the treatment should be the same as that which would be pursued apart from the presence of the associated condition.

THE COMMITTEE OF FIFTEEN UPON THE TENEMENT-HOUSE BILL.

The Medical Record on various occasions has voiced its strong approval of the tenement-house bill now before the legislature. The passing of a measure of this nature will assuredly have the effect of checking disease and will prove an effective means of raising the standard of health throughout the entire city. But this is not the only benefit it will confer upon the citizens of New York. Regarded from the point of view of good morals, its passage will act as potently in curbing vice as it will in preventing disease. The committee of fifteen looking at the matter through "their spectacles" has written a letter to Governor Odell in which its members embody their views on the subject. The letter in part says that "At a meeting of the committee of fifteen held March 6, 1901, a resolution was unanimously adopted declaring the adherence of the committee of fifteen to the views of the tenement-house commission in regard to the social evil in tenement houses, and earnestly approving of sections 141 to 151, inclusive, of the act relating to tenement houses in the city of New York, proposed by said commission." The committee then proceed to give their opinions on the existing condition of affairs which are asserted to be not only deplorable but intolerable. Attention is drawn to the fact that the worst and saddest feature of the case is the prostitution of children, rendered possible by the pollution of the atmosphere by degrading forms of moral evil in the tenement district. It is pointed out that the statistics of disease due to vice show that such diseases are increasing at a rapid rate among children in the crowded sections of this city, and that the laws at present upon the statute books have so far not met the situation with regard to the restraint of prostitution. It is consequently urged that the social evil must be extirpated from the tenement houses.

The committee believes thoroughly that the legislation as proposed by the tenement-house commission is sound and likely to have the desired result.

The proposed law makes the penalty for allowing any part of a tenement house to be used for immoral purposes $1,000 which shall be a lien on the property. Undoubtedly the tenement bill if it become law will do incalculable good, and is worthy of the support of all respectable dwellers in New York City.

News of the Week.

John Milton Holt, assistant surgeon of the United States marine service, has been transferred from Cairo, Ill., to Chicago.

Florida Medical Association.—The twenty-eighth annual meeting of the Florida Medical Association will be held in the Board of Trade Building, Jacksonville, Fla., Wednesday, April 10, 1901.

Department of Charities not Able to Pay Medical Examiner.—Dr. Abraham L. Lewis, a medical examiner of charitable institutions in the Department of Public Charities, in Brooklyn, has been relieved of his position. The reason, according to Commissioner Goetting, is "insufficient appropriation for salaries." Dr. Lewis' pay was $1,000 a year.

The Eastern Medical Society held its annual banquet at the Hotel Marlborough on Saturday evening, March 23d. The large banquet hall was well filled, mostly by members and their wives and a few invited friends. After-dinner addresses were made by Dr. L. J. Ladinski, chairman of the arrangement committee, who acted as toastmaster, and called on Dr. A. Jacobi for the first address. Dr. Jacobi spoke at first very wittily and ended very seriously on the subject, "Roads to Success in the Practice of Medicine." He was followed by the Rev. Dr. S. Schulman, who spoke on the relations of the clergyman to the physician, and dwelt very eloquently on the social conditions of the lower East Side, the home of the society. Dr. A. E. Isaacs, the president, spoke for the society, as to the causes that brought it into existence and its prospects for the future. He stated that its membership had recently risen over the three hundred mark, and that it included over ninety per cent. of the physicians of the lower East Side; that great results were hoped for from this large membership, one being the establishment of a

local medical library. Dr. William S. Gottheil closed the speaking with a toast to the ladies. The dinner was followed by an informal dance, which proved to be a very agreeable feature of a most pleasant affair.

Philadelphia Neurological Society.—At a stated meeting held March 25th, Dr. F. X. Dercum exhibited "A Case of Traumatic Epiphysitis" in a man thirty-seven years old, who presented considerable shortening of one upper extremity, due to abbreviation of the humerus, which, it was thought, had resulted from inflammation of the upper epiphysis and premature union with the diaphysis of the bone, in consequence of injury. Dr. Dercum stated that he had seen two other cases of similar character following infectious disease in childhood. The patient complained further of a number of painful points on the shoulder, the neck and the orbits, and the possibility of the coexistence of hysteria was suggested. Dr. A. R. Moulton reported "A Case of Fracture of a Thin Skull and Hemorrhage into the Brain." The patient was an insane man, fifty-nine years old, who, shortly after his reception into the hospital, was in the morning found dead on the floor of his room beside his bed, apparently as though he had become entangled in his clothing and had fallen. On post-mortem examination the skull was found exceedingly thin—from $\frac{1}{50}$ to $\frac{1}{32}$ inch in thickness—in places, especially on the floor of the posterior fossa and at the sides above and behind the external auditory meatus. The base of the skull was fractured in two places. The left frontal and the right parietal and occipital regions were covered by large blood clots and an area of degeneration was found in the left cerebellar hemisphere and the left frontal lobe of the cerebrum. Dr. Charles Potts exhibited "A Case of Multiple Sclerosis, with Unilateral Ascending Progressive Paralysis." The patient was a young man, nineteen years old, who presented symptoms of right hemiparesis, with exaggerated knee jerks, ankle clonus, Babinski's sign, nystagmus, transitory diplopia, slight thickness of speech, and pallor of the optic discs, of comparatively recent development. Dr. Alfred Gordon read a paper entitled "The Rôle of Infection and Intoxication in Diseases of the Spinal Cord," pointing out the frequency with which this presumably etiological association can be discovered if carefully looked for. Dr. William C. Pickett read a paper entitled "The Scapulo-Humeral Reflex of von Bechterew," in which he detailed the results of observations in one hundred and twenty-two cases, principally of various forms of organic disease of the nervous system. The reflex was found increased in the presence of lesions of the upper (corticospinal) segment, including the pyramidal tract, while it was diminished or absent in the presence of lesions involving the reflex path, including the gray matter of the posterior columns. It may be considered the analogue of the knee jerk, although it is less constant than the biceps jerk and the triceps jerk. Its mechanism is, however, so complicated and so obscure that as yet too much confidence should not be reposed in its localizing value. Dr. Moses Behrend, by invitation, read a paper entitled "The Biceps-Tendon Jerk in Locomotor Ataxia," reporting the results of observations in twenty-nine cases, in which he failed to find correspondence between the biceps jerk and the knee jerk, the former being not rarely present when the latter was absent.

Reception to Dr. C. L. Dana.—A reception was tendered, on March 29th, by the Philadelphia Medical Club to Dr. Charles L. Dana, of New York, after a dinner by the president of the club, Dr. E. L. Duer.

Entertainment in Aid of the Blind.—An entertainment will be given at the Waldorf-Astoria, on the afternoon of April 12th, in aid of the Home of the Blind. Coquelin and Plançon will entertain.

Extirpation of the Stomach Performed in New York.—At the German Hospital, St. Nicholas Avenue, Brooklyn, this operation was performed on March 29th by Dr. George R. Fowler upon Jacob Wichman. The patient had been suffering for a considerable time from cancer of the stomach, and it was recognized that an operation was the last resort to save life. A number of prominent physicians witnessed the operation, which lasted three hours. It is said that the patient stood the operation well, although he died quite suddenly three days afterward.

Court Held in Hospital.—St. Catherine's Hospital, in Brooklyn, was the scene of an uncommon occurrence on Friday, March 29th. Some four weeks ago Samuel Earl shot himself with a revolver in the head and left shoulder. He was arrested and taken to the hospital, where the wounds healed, but pulmonary tuberculosis developed. Earl had to answer the charge of attempted suicide, but as he was in no fit condition to be removed, the magistrate proceeded to the hospital, accompanied by the court officers. The man pleaded guilty, but said that he was distracted by thinking of his hard luck, and was not responsible for his action. The complaint was dismissed.

Pathological Society of Philadelphia.—At a stated meeting held March 28th, Dr. William G. Spiller read a communication entitled "Cerebellar Lesions Without Cerebellar Symptoms," with a report of illustrative cases. Dr. David L. Edsall reported "A Case of Malignant Endocarditis," and exhibited the specimens. Dr. Milton B. Hartzell reported "A Case of Pigmented Epithelioma or Alveolar Melanotic Sarcoma" and "A Case of Peculiar Degeneration of the Epithelial Cells at the Margins of an Ulcer." Dr. W. B. Eaton presented a communication on the "Histogenesis of Myomata." Dr. A. Newlin exhibited specimens from "A Case of Sarcoma of the Lung," in a man in whom the primary lesion had appeared some six years previously in the scapular region. There was found also a large fibroid tumor attached to the capsule of the spleen. Dr. A. V. Meigs presented a communication describing the changes induced in blood-vessels as the result of shrinking due to methods of preservation. By introducing cylindrical bits of glass into vessels on post-mortem examination, and thus keeping the lumen free and preventing shrinking, without distention, the plicated membrane was shown

to have no existence as such, and certain other distortions observed in the muscular layer were not present. In each instance a portion of the same vessels was treated in the ordinary manner, as well as kept patulous by means of the glass, for purposes of comparative observation. Dr. Meigs demonstrated also the development of blood-vessels in the wall of a vein.

A Hospital for the Bronx.—The assembly on March 29th passed Senator Hennessey's bill, providing for the construction of a hospital by New York City, in the Borough of the Bronx, the cost not to exceed $200,000.

Honors for Professor Grassi.—The Society of Italian Agriculturists has awarded the Golden Crown, bestowed upon those who have deserved well of agriculture, upon Prof. Giambattista Grassi for the valuable services which he has rendered agriculture by his investigations on malaria.

A Permit Necessary to Practise Hypnotism in Hungary.—The government in Hungary has issued an ordinance forbidding hypnotism to be practised without a special permit from the Sanitary Department. This step has been taken to deprive criminals of the opportunity to plead hypnotic influence as an excuse for wrongdoing.

Convicts in Virginia.—Conditions in the Virginia penitentiary, as described by Dr. Charles V. Carrington, the physician at the institution, are fully as bad as those which required legislative correction in Georgia, Florida, and other of the Southern States. Both body and soul are ruined in the Virginia prison. The faulty, antiquated construction of the buildings and their crowded condition make impossible the provision of ordinary means for the preservation of health. In the prison for men an average number of one thousand two hundred convicts are confined in one hundred and ninety-two cells; and pure air is, of course, unknown. There is no sewerage system except in the hospital. The food is of poor quality, and the manner of its distribution makes it worse. It is taken by the prisoners from a board in the yard as they pass by in single file, and in the winter the men often find their miserable portion frozen. Only the fact that the criminals are generally young, vigorous, and accustomed to privations prevents the annual death rate from rising above forty per thousand. By the congregate plan in vogue, hardened criminals are thrown together with young offenders. Lessons in crime are the result, and vice for which the cities of Sodom and Gomorrah were destroyed.

Philadelphia County Medical Society.—At a stated meeting held March 27th, Dr. C. A. E. Codman read a paper entitled "The Acquired Form of Funnel Chest." Dr. M. G. Tull reported "A Case of Arthritis Deformans Successfully Treated by Application of Ice to the Spinal Column," and exhibited the patient. Dr. W. C. Hollopeter read a paper entitled "Fangotherapy," and related several cases in which relief was afforded by the local application of the volcanic form of mud or slime known as fango. This putty-like substance is obtained at some of the Italian health resorts, and makes a somewhat neat moist dressing, which retains its heat well. Dr. I. Newton Snivley read a paper entitled "Treatment of Croupous Pneumonia by Antipneumococcic Serum," describing several cases in which the employment of this agent was apparently followed by curative results.

The Bell Medical Bill, according to latest reports from Albany, will not be reported by the legislative committee, neither will the bill providing for the licensing of osteopathy.

Successor to Dr. Jacob.—Dr. Henry Jellett, ex-assistant master, Rotunda Hospital, Dublin, has been appointed editor of the *Medical Press and Circular*, in succession to the late Dr. Archibald Hamilton Jacob, and Dr. Foy has been given the post of assistant editor.

Russia Bars Women Medical Students.—As a result of the recent student riots in St. Petersburg all the higher courses for women in the Medical Institute of the University of St. Petersburg have been closed indefinitely by official orders.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy, for the week ending March 30, 1901. Assistant Surgeon R. E. Ledbetter detached from the *Constellation* April 1st and ordered to the *Chicago*, via the *Dixie*, April 3d, as relief of Assistant Surgeon J. R. Whiting. Assistant Surgeon C. A. Crawford detached from the *Dixie*, March 28th, and ordered to the *Constellation* April 1st, as relief of Assistant Surgeon R. E. Ledbetter. Assistant Surgeon J. R. Whiting detached from the *Chicago*, upon reporting of relief, and ordered to the *Dixie*. Surgeon G. Pickrell detached from the naval hospital, Mare Island, Cal., and ordered home. Assistant Surgeon E. Davis detached from the naval hospital, Mare Island, and ordered home, with permission to delay *en route*. Assistant Surgeon R. K. McClanahan ordered to the Asiatic Station, via the *Solace*, April 12th. Surgeon C. J. Decker, order detaching from the *Monocacy* and ordering to the *Oregon* revoked; ordered to the *Newark*. Surgeon P. Leach, order detaching from the *Oregon* and ordering to the *Monocacy* revoked. Surgeon C. T. Hibbett detached from the *Newark* and ordered to the naval hospital, Cavite, P. I. Passed Assistant Surgeon R. Spear detached from the *Isla de Luzon* and ordered to the *Concord*. Passed Assistant Surgeon S. G. Evans detached from the *Concord* and ordered to the *Monocacy*. Assistant Surgeon E. J. Grow detached from the *Glacier* and ordered to the *Isla de Luzon*.

McGill University, Montreal.—Dr. J. G. Adami, professor of pathology at this university, has been appointed vice-president of the section of pathology and bacteriology of the International Congress on Tuberculosis, to be held in London in July, under the patronage of King Edward. Dr. Adami will attend.

Census Enumerators in Canada to be Vaccinated.—The New York *Evening Post*, March 25th, states that the chief census commissioners throughout the

Dominion have been instructed by telegraph to order the vaccination of all the enumerators under them. There is believed to be a lot of what is called "walking smallpox" or a mild form of the disease, in different parts of the country, and vaccination is resorted to as a precautionary measure.

British Congress on Tuberculosis.—This congress, says the *Sanitary Record*, which is to be held in the Queen's Hall, Langham Place, in the week beginning July 22, 1901, has arranged amongst other matters for three public addresses to be delivered in the large hall, on Tuesday, Wednesday, and Thursday of that week. The first will be given by Prof. Robert Koch, of Berlin, discoverer of the tubercle bacillus, the second by Professor Brouardel, of Paris, and the third by Professor McFadyean of the Royal Veterinary College, London.

The New York American Medical Association Special.—Arrangements are being made for a special train from New York to carry those who desire to attend the meeting of the American Medical Association in St. Paul, June 4th–7th. Persons residing in New York City or its vicinity who contemplate attending this meeting should communicate without delay with the secretary of the New York State Medical Association, Dr. Frederick Holme Wiggin, 55 West 36th Street, New York.

Progress of Medical Science.

New York Medical Journal, March 30, 1901.

Tropical Dysenteries.—By S. M. Long. The author finds five types of the disease; the fulminating catarrhal, the simple acute, the amœbic (subdivided into the simple amœbic, the trichomonadic, the cercomonadic, and the mixed), the chronic, and the diphtheritic and gangrenous. The sequelæ of the disease as met in the Philippines are: (1) Its chronicity; (2) chronic gastritis and indigestion; (3) obstinate constipation; (4) paralysis (partial) of the large intestines, due either to obliteration of the glands and lack of secretion or to lack of innervation and blood supply; (5) anæmia, from lack of assimilation of food; (6) the association with it of malarial fever; (7) typhoid fever; (8) neuritis; (9) atrophic cirrhosis of the liver; (10) chronic parenchymatous nephritis; (11) abscess of the liver; (12) metastatic abscesses of other organs, as of the lungs and kidneys; (13) inanition; (14) toxæmia; (15) dilatation of the stomach and intestines. For treatment the author advises reliance, in the army service at any rate, on calomel with sulphate of magnesium, ipecac given with an opiate, and bismuth subnitrate. For bowel irrigation he prefers hot water to cold. He prefers solutions of silver nitrate, gr. xx. to the pint, for ordinary cases and quinine for the amœbic cases.

Congenital Dislocation of the Shoulder, with Report of Two Cases of Dislocation Posteriorly.—By D. W. Marston. The author concludes his paper with the following observations: It is of the utmost importance to distinguish between cases of dislocation and true obstetrical paralysis. The treatment of the former condition is immediate reduction; by manipulation if possible; otherwise, operative. Every infant should be carefully examined at birth, for it is at this time that reduction is most easily performed. From the facts that a fracture of the glenoid cavity was found in three cases, and that the history of nearly all cases shows difficult labor, he is led to believe that these cases are not of paralytic origin, or due to non-development, but are due to traction made in the axilla by the finger or vectis, or to the arm being caught in some unusual position and dislocated by the contraction of the uterus. Paralysis may be coincident, but it cannot be a primary factor in causing dislocation posteriorly. The prognosis of the operative treatment is excellent. The earlier the operation, the more hopeful the outlook. Like congenital dislocation of the hip, these cases of the shoulder are little benefited by mechanical treatment.

A Requisite to Increase the Usefulness of Ambulances.—F. Griffith believes that the construction of ambulances is too open for the freezing weather common to northern cities. He thinks that the vehicle could be kept much warmer by the use of asbestos or some other non-conductor of heat in the frame of the top, bottom, side walls, and doors. When steam is the motive power for propulsion the exhaust steam could be turned into coils which would warm the interior; a similar result could be obtained from electricity. In the old type of ambulance drawn by horses a small stove should be carried. By these measures shock to the patient from an injury could be greatly lessened. It is also practicable to carry heated sand bags which could be laid alongside of the patient's body.

The Causes and Significance of the Obstetric Hemorrhages.—By J. C. Edgar.

The Pathology of Intra-Uterine Death.—A continued article by Neil McPhatter.

The Comparative Pathology of the Jews.—By M. Fischberg.

A Dressing for Colles's Fracture.—By C. L. De Merritt.

The Boston Medical and Surg. Journal, March 28, 1901.

A New Method of Treating Fractures.—Leonard F. Hatch says that his principle (a part of it old but not followed generally, the other never having been used nor advanced to his knowledge) is to convert all compound fractures into simple ones; the other is to operate on simple fractures, making them compound and then apply the first principle, making them simple. He gives the technique of his operations and reports fifteen cases of successful results. His deductions are, that (1) with the advance made in modern surgery, seeing that we do not hesitate to enter the abdominal or cranial cavities (in some cases even simply to establish a diagnosis) we should not be deterred from operating on fractures by fear of sepsis, and it certainly is unscientific to adopt a blind way when a better presents itself. (2) It would be warranted if it did nothing more than to relieve the pain and swelling, which it certainly does. (3) It shortens the repair process at least one week. (4) It reduces the chances of deformity and non-union to a minimum.

The Embryological Basis of Pathology.—Charles Sedgwick Minot, in an address to which it is impossible to do justice in an abstract, divides his subject into (1) normal differentiation, and (2) pathological differentiation. Under the first head he discusses the undifferentiated cell, the progress of differentiation, and the changes which may succeed differentiation. Under the second heading he develops these general propositions: (1) That each germ layer has a specific and exclusive share in the production of tissues; (2) that undifferentiated cells, characterized by having only a small amount of unspecialized protoplasm, exist not only in the embryo, but also throughout life, in certain parts of all three germ layers; (3) that differentiated cells, characterized by having a larger amount of specialized protoplasm, form most of the organs of the adult, and are incapable of undergoing any new unlike differentiation, though they are still capable of completing their cytomorphosis, by necrobiosis or degeneration.

Nine Cases of Lobar Pneumonia Treated by Ice Pack.—George L. Collins says that in only one case did the ice pack cause discomfort. In no case was the crisis accompanied by dangerous collapse. High temperature (and not physicial signs) has been in each case the indication for application of ice; low temperature, the indication for its removal. The average fall of temperature was 4.5°. In all but one case this fall was within forty-eight hours of application of ice. The white count invariably began to fall with the temperature, but reached normal in no less than one week after the temperature was normal. The ice pack had apparently no particular effect in shortening or prolonging the duration of physical signs. These cleared on the fourteenth day.

Mumps in Pneumonia; Boroglyceride.—Charles W. Dulles treated a case of mumps by the application of a fairly thick compress of surgical gauze saturated with boroglyceride, and covered with a layer of paraffin paper and just enough bandage to keep it in place. Relief of pain and the subsidence of swelling promptly followed the application. The author uses boroglyceride in a variety of inflammatory swellings, and since its use has not had to apply a knife to boil or carbuncle.

Medical News, March 30, 1901.

Vaccination, Clinically Considered.—Frank S. Fielder emphasizes among other points the following: Complete natural immunity to vaccination is practically unknown. In primary cases, delayed vesiculation, raspberry excres-

cence, and abortive course mean poor virus. There is now no danger of transmitting syphilis or tuberculosis. During the second week of vaccinia a large painful areola may be considered normal if it be bright red and if the vesicle be of typical appearance. If the vesicle be irregular, filled with greenish pus, and the areola be of a dark livid, purplish hue, the case is one of mixed infection. Immunity is acquired about the time the areola is at its height—eight to ten days after vaccination. Vaccination of the pregnant woman does not protect her child. The duration of immunity to smallpox, which is conferred by vaccination, is extremely variable. Of persons successfully vaccinated within five years, very few will contract the disease; but some will, though they will probably have varioloid instead of severe smallpox. The duration of immunity to revaccination is also extremely variable, and is probably two years or under. The quality of a scar is a fair indicator of its protective power against smallpox. Revaccination protects against smallpox as fully as an attack of the disease protects against a subsequent attack. Revaccination should be considered as important as primary vaccination, and should be just as systematically practised. Primary vaccination should be performed in infancy, revaccination at school age. In the presence of an epidemic, however, revaccination should be performed even though the primary vaccination was of comparatively recent date. All vaccine virus should be subjected to rigid physiological tests before issuance. It should be retested monthly so long as it is on sale. Vaccination should be performed aseptically. Shields often do more harm than good. If signs of mixed infection appear, the vesicle should be opened, the wound cleansed, and treated upon general surgical principles.

The Method of Preparation of Vaccine Virus in the Vaccine Laboratory of the New York City Health Department.—By J. H. Huddleston.

The Jour. of the Amer. Medical Ass'n, March 30, 1901.

Sanitary Conditions of Peking.—John Inglis says that the population of Peking is now close to the million mark. A study of the sanitary conditions of that city reveals much of a threatening nature. The city is without water works, and has no sewerage system worthy of the name. The Chinaman believes in open sewers. The water supply is from wells dug along the sides of the streets. The water itself is of two kinds, "sweet" and "bitter," the latter with an excess of alkali and containing twenty-two per cent. of hardness. The use of this water means a great deal of kidney trouble. There are no alleys. In front of meat shops the animals are killed. Dogs are the city scavengers. There are no cellars. The city is infested with beggars, ill-clad and filthy beyond description. As to the disposal of the dead, if the deceased be wealthy the corpse is kept in the courtyard for weeks. The itinerant barber is a prolific spreader of diseases. An American bishop, who visited Peking recently, stated that, on entering the city, he distinguished seventy-two distinct odors. Sanitary science should be applied in Peking, and would make it as healthy a city as New York or Chicago.

Recent Advances in Dermatology which are of Service to the General Practitioner.—L. Duncan Bulkley states that of late years considerable progress has been made in the way of recognizing various inflammatory conditions of the skin under the general name dermatitis, and much that was formerly classed as eczema is now thus designated. In the pathology of skin diseases there has been considerable activity of research, and clearer views are obtained each year in regard to many affections. As to the newer remedies in skin diseases, resorcin and ichthyol have more than held their own. Light, as found in the *x*-rays and the so-called Finsen phototherapy, is among the newer therapeutic agents from which much has been expected. It is probably too soon to form a correct estimate of the value of this treatment. The author believes that although dermatology is such a difficult field, yet a reasonable amount of study and observation, with judgment, will enable the general practitioner to utilize many of the advances which are continually being made in this specialty.

Pathological Conditions Found in Meat Inspection.—D. E. Salmon states that our inspectors are instructed to condemn: (1) All carcasses affected with generalized tuberculosis; (2) all carcasses with extensive localized tuberculosis, and (3) all carcasses with localized tuberculosis, that show signs of emaciation. This ruling is considerably more stringent than the European practice. The nodular disease of the sheep's intestine is an interesting one. This is very common and apparently affects the sheep's health only when the nodules are so numerous as to interfere with the assimilation of the food. Another disease to be noted is actinomycosis with its lesions in the jaw, tongue, liver, lungs, and udder. In this country the process most frequently affects the maxillary bones. This disease is probably not transmitted from animals to man, so the carcasses are condemned only when there is emaciation or when the system is affected at large. The author then considers the animal parasites.

Venereal Disease as a Social Problem.—W. C. Gates believes that much of this evil can be prevented. The acme of medical science is the prevention of disease. Prostitution has existed under every social system of which the world has knowledge. While it may be a necessary evil under the present social system, many of the resultant evils are not necessary and may to a great extent be prevented. Social purity should be one of the ideal aims of society, and the author believes its nearest attainment will be found through the means of education. More thorough instruction should be given in sexual hygiene and physiology in our medical schools. Medical men can have great influence in this field.

Circumcision in Restricting the Spread of Syphilis.—Harold N. Moyer calls attention to statistics which show that if circumcision were universally applied there would be a lessening of the most disastrous of venereal diseases from fifty to seventy-five per cent. He believes the operation to be a practical means of reform, ready to hand. Its application is within the reach of every physician.

Report of the Special Committee of the Section on State Medicine of the American Medical Association, Appointed to Inquire Whether and When the Gonorrhœic may be Permitted to Marry and Whether the Matter is a Proper One for Regulation by Statute.

Quantitative Tests for Proteolysis.—A. L. Benedict concludes his article this week and tabulates a number of cases.

The Rage for Rapid Operating and the Importance of Saving Time in Surgical Operations.—By John S. Miller.

Purulent Otitis; its Treatment and Prevention by the Family Physician.—By H. Gradle.

Operations for Injuries to the Median and Ulnar Nerves. By R. Brindley Eads.

The Treatment of Prolapse of the Rectum.—By Joseph M. Mathews.

Open Treatment of Suppuration of the Knee Joint.—By W. J. Mayo.

Acute Suppurative Folliculitis of the Scalp.—By William S. Gottheil.

Thyroid Tissue in the Larynx and Trachea.—By Otto T. Freer.

Philadelphia Medical Journal, March 30, 1901.

How to Prevent Stammering.—G. Hudson Makuen declares that the time to cure stammering is before it begins. Few, if any, children stammer from the very outset. There are three mechanisms of speech: the respiratory, the vocal, and the oral. Most stammerers can employ any one of these separately, but the trouble comes in attempting to do these three things at the same time. They are unable to co-ordinate the action of the three mechanisms of speech. This faulty co-ordination is generally due to a faulty action of one of these mechanisms, which always results in a faulty action of them all. The trouble generally appears in the respiratory and vocal mechanisms, and the spasms of the articulating muscles are due to the overflow of nerve energy into these parts. The primary cause of this affliction is probably located in the motor speech centres of the bulbous portion of the spinal cord. It is probably a structural condition, differing slightly from the normal. In many cases the tendency to stammer is inherited. Stammering is generally of slow development and begins during a period of great excitement. The child should not be scolded or imitated or allowed to associate with stammerers. The mental processes should be directed into normal channels. Children should never be allowed to stammer and the habit should never be formed.

The Coexistence of Carcinoma and Fibroma in the Corpus Uteri.—W. A. Newman Dorland, from the study of this subject, concludes: That it is possible for fibroma and carcinoma of the uterus to coexist; and that this coexistence may manifest itself in one of three distinct ways, as follows, given in their order of frequency: (1) Fibromyoma of the corpus uteri with carcinoma of the cervix; the increased vascularity of the uterus and the irritant leucorrhœal discharges attendant upon the benign tumor favoring, in those women so predisposed, the development of cervical malignancy. (2) Fibromyoma of the corpus uteri with associated adenocareinoma of the endometrium, the malignant disease not invading the benign tumor, but originating either in the tubular utricular glands or in the included glandular vestiges which may be present. (3) True cancerous degeneration of an adenomyoma, the malignant change originating in glandular vestiges, included

in the uterine growth, or the carcinomatous disease invading the benign growth by extension from an endometrial adenocarcinoma through contiguity of tissue.

Diseases and Disorders of the Heart and Arteries in Advanced Life.—Second Lettsomian lecture, by J. Mitchell Bruce. The special topics considered in the lecture are the heart in tobacco poisoning, alcoholism, gout, bodily strain, and syphilis. Syphilis appears to account for a very considerable proportion of the more serious cases of heart disease met with in older subjects, of course excluding chronic valvular disease originating remotely in endocarditis; but syphilis as a cause of cardiovascular lesions is very often associated with other morbific influences, particularly strain and alcohol. Of its position as the principal cause of serious disease of the valves, as distinguished from the walls of the heart, originating in middle life, there can be no question. No fewer than nine out of twenty-eight patients of whose cases the author has notes were the subjects of double aortic disease; practically all the others had a loud ringing second sound over the aorta, significant of degeneration; pain of anginal type in half the cases was the prominent complaint; and two-thirds of the subjects had sclerosis of the radial artery. When we consider that syphilis does also affect the myocardium primarily, that fibroid disease, chronic aneurism, and fatty degeneration of the heart are all traceable to specific disease of the coronaries in many instances, and finally, that many of the subjects of syphilitic cardiovascular disease have perished before the age of forty years, the magnitude of this cause can be fully realized. The profession in general are not yet awake to the gravity of this subject. Reference is made to a paper published thirteen years ago by Mott on twenty-one cases of sudden death from cardiovascular disease, and in nine of these there was a history of either actual or probable syphilis. What was of greater interest, however, at that early date, was that he drew attention to the association of syphilitic cardiovascular lesions with Bright's disease, in the broad acceptation of the term.

Three Cases of Acute Diffuse Septic Peritonitis Resulting from Appendicitis; Operation; Recovery.—By W. G. Richardson. In discussing the cases the author says that if the rule be followed to remove the appendix in very acute cases which at the end of twenty-four hours do not improve in all the symptoms—a large number of lives will be saved which are often, perhaps usually, lost through the operation being performed after perforation has taken place. At the same time, it is obvious that by applying such a rule a number of cases will be operated on in which, although the appendix is on the point of giving way, it is yet guarded by adhesions. Against this must be placed the risk of waiting and the possibility of abscess formation, and above all the simplicity and safety of operating at this stage must be taken into account. This, however, must not be made an excuse for a hard-and-fast rule of treatment that all cases of acute appendicitis must be operated on. Surely that is not sound surgery. If the appendix has perforated and general peritonitis has become established, it is then a matter of supreme importance to operate without any unnecessary delay—unless the abdomen is distended with flatulent intestines or the hands are cold and red, when it is best not to operate at all, as there is evident general vascular and nerve failure and any operation could only hasten death. In the first few hours of acute general peritonitis the distention is not due to gas in the intestines, but to a collection of thin milky-looking pus in the general peritoneal cavity; whereas in the later stages there is little or no fluid and the distention is due to gas in the intestines, which are then dark-colored, dry, and sticky, with adherent lymph on the peritoneal surfaces, suggesting that the wall of the intestine has played the part of a sieve, allowing the fluid to pass through but retaining the solid portion of the pus as a covering of lymph.

The Elimination of Arsenic through the Hair and its Relation to Arsenical Poisoning.—By W. F. Dearden. Samples of hair taken from six males were submitted to analysis. Two were from well-marked cases of arsenical beer poisoning, another from a patient who had been taking one-ninth of a grain of arsenic per diem for an extended period, and three from healthy individuals, aged respectively sixteen, twenty-three, and thirty-five years. In the three last-named samples arsenic was found to be present, but in quantities too minute to be estimated in one gram of substance. The sample from the patient who was taking the drug medicinally was found to contain arsenic in the proportion of 0.3 in 10,000. One of the two patients who were the subjects of arsenical beer poisoning had present in his hair arsenic to the extent of 0.3 in 10,000, whilst the other showed the much larger proportion of 1 in 10,000. The vast difference in the proportions found between these samples and the three healthy samples shows in a marked manner the value of chemical analysis of the hair from a diagnostic point of view. The method employed in the estimation of arsenic in the samples referred to above was Sanger's modification of the Marsh test.

Blackwater Fever.—J. W. W. Stephens concludes that blackwater fever is essentially a malarial infection in which quinine is the most common immediate determining cause of intoxication. Protection from malaria will insure protection from blackwater fever. Complete protection from malaria may, as the author's two years' experience in tropical Africa under all conditions shows, be attained without the taking of any quinine, by paying scrupulous attention to the clothing, and by the use of the mosquito net.

British Medical Journal, March 23, 1901.

A Clinical Lecture on the Diagnosis and Treatment of Intussusception.—Charles P. B. Clubbe states that the attack occurs quite suddenly, the child generally screams, seems faint, turns pale, and a few hours later passes blood. The "sausage-shaped" tumor is nearly invariably felt in cases of intussusception. This trouble may be present while all its usual symptoms are absent. As soon as the diagnosis is made the treatment should be begun. If the child belongs to poor people, it should be sent to the hospital at once. The author believes injections to be both useful and safe. They may consist of warm oil or water. The operation is then described. The after-treatment is important. A baby must be fed after the first few hours. Mellin's food, or whey and water, or the white of egg in water with a little somatose may be given in small quantities. Nearly all children will require morphine in very minute doses during the first twenty-four hours. Strychnine and digitalin are often indicated. Calomel may be given if the bowels are not open after the first twenty-four hours. The silkworm-gut sutures must never be removed before the tenth day.

A Case of Gastric Fistula; Operation; Death.—C. F. M. Althorp reports a case in which the index finger could be easily passed through the fistula into the stomach. An incision was made above and to the right of the fistula. The interior of the stomach was found free from disease except near the fistula. The latter appeared to be the centre of a large ulcer, situated near the pylorus, on the greater curvature. The edges of the fistulous opening in the stomach were freshened and three rows of silk sutures inserted. Over all, a piece of omentum was drawn and stitched. The wound was sutured and the patient appeared to do well till she developed pneumonia and died on the sixth day.

Perforated Ulcer of the Stomach.—William H. Horrocks reports this case with the following points of interest: The absence of any indication of gastric ulcer before perforation. The ulcer was near the cardiac end and close to the lesser curvature. There was no apparent exciting cause for perforation. The pain and tenderness correctly localized the position of the ulcer, and the marked tension of the abdominal wall at this part made the diagnosis more certain. The repeated movements of the patient spread the extravasated material over the whole abdomen. The cleansing power of the peritoneum over its lower zone was markedly shown.

Four Cases in which the Murphy Button was Used.—G. P. Newbolt gives the history of these cases, and states that his experience of the button, as far as it goes, is favorable. In each case he used Lembert sutures over the button. He does not believe that any patient would get rid of the button with knowing it had passed.

Revue de Chirurgie, March 10, 1901.

Torsion of Hydrosalpinx. — Fernand Cathelin concludes that the torsion of hydrosalpinx is merely a special example of the general law governing the torsion of organs and of abdominal tumors. It is noted with the greatest frequency between the ages of thirty and forty, and occurs most often on the right side. The mechanism of torsion depends upon various causes, such as a peripheric external tubal seat of the tumor, a long and slender pedicle, excessive mobility, abdominal, non-pelvic situation, growth from above, or pressure and contraction of the intestines, and a very sloping superior strain. Prognosis is grave unless operation is performed, as secondary pyosalpinx is likely to occur. Laparotomy, with bilateral castration and secondary hysteropexy, without drainage is the preferable procedure.

Unilateral Exclusion in Obstinate Intestinal Fistula.—X. Delore and M. Patel extol this operation, which consists in the partial exclusion of a portion of the intestine, which is ligated at its distal end only. When performed on the small intestine, the results are the same as in entero-anastomosis; that is to say, fecal matter accumulates in the lower segment, and the fistula persists. In the large intestine, however, the results are often curative. Circulation of the fecal matters is obtained as in bilateral exclusion, the purulent fistula has no further excuse for existence, and there is but little risk of infection by propagation.

Chopart's Amputation.—André Lapointe gives a long and detailed account of this operation. He considers it an excellent process for the partial amputation of the foot, and the one to be chosen whenever possible. It has not yet been demonstrated that either Syme's or Pirogoff's operation has any greater orthopedic value.

Fractures of the Upper Jaw.—By R. Le Fort (a continued article).

Revue de Médecine, March 10, 1901.

Hysterical Anæsthesia.—Bernheim, of Nancy, says that hysterical anæsthesia is purely psychical, its characteristics being the same as those of anæsthesia due to suggestion. It is less frequent than usually supposed. It is always amenable to psychotherapy, but the latter is often interfered with by the autosuggestive resistance of the patient. It may have an organic origin, as peripheric or central vasomotor paralysis or constriction, and remain as an autosuggestion after the vascular trouble has disappeared, Organic hemianæsthesia of cerebral origin, from a lesion in the neighborhood of the posterior third of the posterior segment of the internal capsule (*carrefour sensitif*), may also survive the lesion by means of autosuggestion. Sensory impressions are perceived and recognized during psychical anæsthesia. But the mind, affected by the idea of anæsthesia, acts in an inhibitory way and effaces the sensation as soon as it is perceived, by amnesia.

Typhoid Fever Associated with Dysentery.—Paul Remlinger reports a number of cases of the association of these two diseases. The prognosis in these cases is very grave. As to treatment, absolute rest in bed, milk diet, saline purgatives, and calomel are indicated in both diseases. Purgatives, judiciously given, are even to be preferred to naphthol, salol, or bismuth salicylate. There is no absolute contraindication to cold baths. If the physician desires to treat the dysenteric mucosa by injections of silver nitrate, the tincture of iodine, or permanganate of potassium, the coexistence of typhoid fever will not forbid. Artificial serum will render the same services in the case of the associated diseases that it does to each singly. Subcutaneous injections of caffeine or camphorated oil and the administration of tonics will sustain the heart and the general system.

Re-education of the Heart Movements by Means of Methodical Exercise.—By Fernand Lagrange (a continued article).

Condition of the Blood in Zona.—By Sabrazés and Mathés.

A Case of Colotyphus.—By Ph. Bourdillon.

French Journals.

Disciplinary Control of Cough in Tuberculous Patients.—F. Lalesque is accustomed to direct the patient coming to submit himself to the climatic treatment, not to cough without expectorating. Although the cough provoked by excitations originating in the various organs is called reflex, the term is not appropriate, since cough is always reflex. The dry cough is without aim—without result. The moist cough has an aim and attains a result—it is useful. The author believes that the dry cough can be suppressed by self-control. The physician should carefully explain to the patient the uselessness of the dry cough, pointing out to him the discomforts attending it, and urging him to exert his will in suppressing it. This will often have the desired effect.—*Journal de Médecine*, March 10, 1901.

Is Alcohol a Food?—R. Romme declares that our knowledge of the physiological action of alcohol and the alcoholic beverages is very limited. In medicine, alcohol passes as an excitant or stimulant—a very vague term. But it really appears from its effects, according to many authors, to be a paralysant. It alters rather than stimulates the functions of the organism. It presents the action of a toxic substance whose effect is more paralyzing than stimulating. Alcohol is not a food properly speaking. It should be considered a condiment. But in order to play this rôle, which is one of considerable importance, it should be sufficiently diluted, and natural, as it is found in a drink naturally fermented such as wine, cider, or beer. In any other form it is a poison.—*La Tribune Médicale*, March 6, 1901.

Prolapse of the Genital Organs.—Duplay speaks of cystocele, rectocele, and prolapse of the uterus. The latter presents three degrees: (1) The uterus has fallen a little into the vagina. (2) The cervix has reached the vulva. (3) The entire uterus has passed outside the vulva. There are acute and chronic cases, the former being very rare. If the uterus is completely prolapsed and irreducible, vaginal hysterectomy is indicated. In certain cases in uterine prolapse alone, recourse may be had to shortening the round ligaments or to hysteropexy. Even in those cases in which vaginal hysterectomy, either total or partial, or Alexander's operation would appear to be indicated, the cure could be completed by elytrorrhaphy and perineorrhaphy.—*La Bulletin Médical*, March 9, 1901.

Münchener med. Wochenschrift, March 5, 1901.

Clubbing of the Fingers and Toes.—A. Dennig recalls the designation of hypertrophic pulmonary osteo-arthropathy given to this affection by Marie, before it was recognized that it could also be associated with diseases other than those of the lungs. Teleky classifies the factors capable of producing the deformity as follows: (1) Diseases accompanied by purulent or necrotic decomposition; pulmonary tuberculosis (with cavity formation), bronchiectasis, empyema, cystopyelonephritis, dysentery. (2) Infectious diseases and chronic intoxications; pneumonia, pleurisy, syphilis, alcoholism (?). (3) Heart lesions, especially when congenital. (4) Malignant tumors; sarcoma and carcinoma of the lung, sarcoma of the parotid. (5) Diseases of the nervous system; syringomyelia, neuritis (?). To this list the author would add, under headings (1) and (2), gastrectasis, basing the assertion on a case observed by him in which relief of the local trouble by resection of the pylorus was speedily followed by a recession of the digital enlargements. He further considers that the clubbing is due to overfilling with blood and hypertrophy of the soft parts rather than to actual growth of bone, though the joint thickening which sometimes is an associated lesion is more often the result of an ossifying periostitis. This view is supported by the fact that, out of ten cases submitted to *x*-ray examination, in only one could any bony hypertrophy be detected.

Clinical Contribution to the Peptic Ulcer of the Œsophagus.—K. Ortmann describes two cases of the œsophagus with secondary cicatricial contraction and dilatation appar-

ently analogous to the common peptic ulcer of the stomach. The possibility of such a lesion is demonstrated by the histological work of Schaffer, who found gastric cell elements mingled with the epithelium of the lower end of the œsophagus. The symptoms are not pathognomonic and comprise dysphagia, regurgitation, pain under the lower part of the sternum, and hæmatemesis. The presence of a stricture not hysterical in nature, not accompanied by the usual manifestations of malignant disease, and giving a distinct impression of cicatricial tissue on the use of the œsophageal bougie, together with the protracted course of the malady, led the author to the diagnosis. In both cases marked improvement followed gradual dilatation with bougies.

Hedonal.—E. Müller, after an exhaustive series of tests, concludes that hedonal in doses of from gr. xxx. to xlv. is a safe and fairly efficient hypnotic. Its most favorable sphere of action is in cases of moderate intensity in which the sleeplessness depends on psychical exaltation, while in severe insomnia it is of little value. Even in milder cases it is often necessary to increase the dose very rapidly, but the system becomes habituated to it so rapidly that very large doses are often as ineffectual as smaller ones. Slight subjective and objective by-effects were noted but seemed not to be of a serious nature, and indicated abandonment of the drug only in cases in which a special idiosyncrasy was present. The most prominent of such symptoms was a very considerable diuresis attended by unpleasant subjective symptoms, but which rapidly subsided on the cessation of medication and left no untoward results behind.

A Case of Unilocular Echinococcus of the Kidney.—A. Meinel reports this case, which occurred in a man aged twenty-one years, whose symptoms pointed mainly to mechanical disturbance of neighboring organs, especially the stomach, by a large-sized tumor in the left renal region. This was elastic, freely movable, and painless, and a provisional diagnosis of hydronephrosis resulting from a movable kidney was made. On laparotomy it was found that the tumor was a renal cyst, which on removal, together with the kidney, proved to be a unilocular echinococcus cyst.

The Technique of Vaccination.—Weichardt employs a lancet of pure nickel, averring that the scarification it produces is less likely to cause bleeding than if a steel instrument be used. For estimating the amount of lymph taken for each vaccination a glass block is used having a V-shaped groove in its upper surface to hold the lymph, while by graduations along the edge it is possible to control the depth to which the inoculating instrument is dipped into the fluid, and hence the amount that adheres to it and is transferred to the patient.

A Reply to Conradi's Article on the Effect of High Temperatures on the Casein of Milk.—By Bienstock.

The Complications of Varicella.—By P. Krause.

A Simple Extension Sling.—By A. Riedel.

Berliner klinische Wochenschr, No. 10, March 11, 1901.

Sterilization of Catheters.—From a series of experiments, Jacob comes to the general conclusions previously advanced by Katzenstein as to the practical utility of formalin vapor for the purpose indicated. Ten minutes' exposure seems a sufficiently long time, provided the catheter is perfectly dry and provided the bacteria to be destroyed are not of unusual virulence. If they are, and if the catheter is moist, fully thirty minutes' exposure is necessary to insure destruction of all bacterial life. For ureteral catheters even the latter duration of exposure at 80–90° is not sufficient, for owing to the narrow lumen and the length of these catheters a longer time is required.

The Therapy of Epithelial Cancers.—O. Lassar records two cases of growths on the nasal alæ, examination of which revealed their cancerous nature. In each instance the persistent use of arsenic in the form of the "Asiatic pill," composed of arsenic and black pepper, effected a cure. Photographs are exhibited of the cases before and after treatment.

The Prognosis of Carcinoma of the Pylorus after Gastro-enterostomy.—By H. Strauss. The consideration of the question is based on the history of a woman aged thirty-five years, who was operated on for the condition named. She made a good recovery from the operation and lived for three years and four months, finally dying from pneumonia. From his personal experience the author is rather inclined to think that carcinoma of the digestive tract is relatively more common in early life than is carcinoma of other organs.

The Progress of the Investigation of Malaria in Italy.—By M. Koch and H. Coenen.

Hæmolysin.—By P. Ehrlich and J. Morgenroth.

Annals of Surgery, April, 1901.

Conservative Operations for Renal Retention.—C. Fenger states that the choice of operation comes into question only in cases of obstruction at the pelvic orifice of the ureter, and lies between transpelvic plastic operation, extrapelvic incision, and plastic operation and pyeloplication. Transpelvic plastic operation may be the operation of necessity in large cystonephrotic sacs because of the difficulty in reaching the ureter outside of the pelvis. In smaller sacs with dilatation of the pelvis he considers extrapelvic plastic operation preferable to resection and reimplantation of the ureter. Resection was practised six times in the cases collated. Twice the operation was incomplete and was followed by nephrectomy. It was successful three times and functionally successful once. One patient died from iodoform poisoning or sepsis. Thus it proved effective in all the four cases in which the operation was completed. Extrapelvic plastic operation was chosen by most of the operators. It was performed eleven times—was successful in ten cases with good functional results, and was unsuccessful in one case. It would thus seem that this should be the operation of choice by reason of the results obtained, and because its technique is relatively simple. The risk to life from this entire group of conservative operations for renal retention is small. Three of the thirty patients died, but in none of them was death due to the operation *per se*. In one case, the patient died from ileus. Two others had bilateral disease, and could not have been saved by nephrectomy. The results of the operations to re-establish evacuation of urine, and thus save the kidney, were as follows: The operation was non-effective in five cases, in four of which nephrectomy was performed with no deaths. In one case a urinary fistula returned. The operation was functionally effective in twenty-two of the thirty cases; that is to say, twenty-two out of thirty kidneys, or seventy-three per cent., have been saved from nephrectomy. In a few of these cases a mucous fistula still remained at the time of publication; but an almost dry mucous fistula, leading probably to a suture or ligature, will close in time, and will never necessitate the removal of a kidney the urine from which passes into the bladder. A statistical table and bibliography accompany the article, and from the former the author's conclusions are drawn.

The Value of the Roentgen Method of Diagnosis in Detecting and Excluding Renal and Ureteral Calculi.—By C. L. Leonard. From the examination of one hundred and thirty-six cases suspected of having renal or ureteral calculi, and the detection of nineteen cases of ureteral and seventeen cases of renal calculus, the author concludes: (1) That both the negative and positive diagnoses by the Roentgen method are accurate and valuable; (2) that ureteral calculus is much more common than has been supposed, constituting about fifty per cent. of all cases of calculus; (3) that it is impossible to arrive at as accurate a diagnosis of calculus by other methods; (4) that this method is comprehensive, and aids operative intervention by localizing all calculi and excluding calculi from the other kidney; (5) that non-operative treatment, without a negative diagnosis by this method, is irrational and dangerous in cases that are at all suspicious; (6) that this method is precise, because its results are mechanically produced, but that accuracy in its employment and care in reading the results are necessary to the avoidance of error; (7) that the data obtained by this method make non-operative, conservative treatment rational in cases of small calculi low down in the ureter, which can be expected to pass; (8) that the negative diagnosis does not preclude exploratory nephrotomy, but does make unnecessary the actual incision into the kidney in search of calculi; (9) that dilatation of the ureter with bougies, as has been practised in the female, may be employed in the male by utilizing a suprapubic cystotomy wound to guide the instruments from the urethra into the ureters.

Ileus due to Vascular Obstruction.—L. L. McArthur enumerates as the four most constant symptoms indicative of ileus caused by embolism mesenteric or thrombosis, the following: (1) Blood seen either in the washings from the bowel, in bowel movements, or in the vomitus, unaccompanied by the tumor of intussusception. (2) Colicky pains, associated with pains in the back and lumbar region. (3) Early collapse if the embolism has been sudden or extensive. (4) Cardiac disturbance, arrhythmia, great frequency, and albuminuria. The history of a case under his own care is then given. The patient died on the table.

The Appendix in Relation to the Psoas Muscle in Three Hundred Male and One Hundred and Eighteen Female Adult Autopsies; Trauma of the Psoas Muscle Produces Appendicitis.—By Byron Robinson. The author's conclusions are expressed in forty-one distinct paragraphs, and space does not afford an opportunity to abstract them here. The paper is freely illustrated and must be read in full by those interested.

Excision of the Cervical Sympathetic Ganglia for Exophthalmic Goitre.—By J. S. Horsley. Notes are given of a case operated on. Horsley claims that this is the first operation for excision of the cervical ganglia for exophthalmic goitre done in America.

Ileus due to Mechanical Obstruction to the Fecal Current.—By D. A. K. Steele.

Ileus Caused by Neoplasms.—By A. J. Ochsner.

Fissure of the Head of the Radius.—By Carl Beck.

Dublin Journal of Medical Science, March, 1901.

A Criticism on the Light Treatment of Lupus.—E. Stapleton has investigated this plan of treatment so ardently advocated by Finsen, and is inclined to be sceptical as to its real value. In the first place he calls attention to the fact that the mucous membranes of the nose and lips have not been found suitable for treatment, partly because the pressure of the apparatus employed to keep the light from hurting the patient cannot be borne and partly because, owing to irregularity of surface, accurate focalization is impossible. Neither can the septum nasi, owing to its inaccessibility, be acted on by the rays of light. Now, as the mucous membranes of the nose and lips and the septum nasi are parts frequently attacked by the disease, this at once establishes a very serious limitation. To get over the difficulty other methods are employed to supplement the light, and, in addition to the usual chemical, mechanical, and thermal agents generally adopted, the *x*-rays are commonly used. The action of the light causes an irritation of the skin, varying in severity from a slight erythema to the formation of vesicles and desquamation. Each time the light is applied an inflammation of the skin is set up which lasts about twelve hours. In Stapleton's opinion it is this inflammatory reaction which brings about the cure when one is effected—the bacteria being killed incidentally. The advocates of the light therapy admit that the early and superficial cases are those which afford the best prospect of cure, but these are just the cases that would naturally be the most amenable to other forms of treatment. Even six months' continuous treatment with the light therapy fails to cure many cases, and the length of time necessary in any case to produce beneficial results is another great objection to the plan. From three to four months are necessary, with a daily attendance of one hour. The apparatus required is very expensive, and its management requires a large force of assistants with special training.

Some Results of the Nordrach Treatment of Consumption in Ireland.—By P. S. Hichens. The Nordrach treatment consists of three things: Abundance of fresh air at all times, day and night, superabundance of food and exercise, graduated according to the state of the body temperature. The results reported are decidedly favorable and the author considers them of interest because they seem to show very conclusively that the cure of consumption does not depend on a beautiful climate and abundant sunshine, but merely on pure country air and a carefully regulated system of life. They have been obtained during a cold, wet summer, and an abnormally wet and stormy winter. They show, indeed, that if doctor and patient were sufficiently determined very good results could often be obtained in the patient's own house. Unfortunately, however, there are but very few patients who will resign themselves thoroughly to this treatment, unless they are isolated from their friends in a sanatorium and associated with others undergoing the same treatment.

Clinical Report of the Rotunda Lying-In Hospital for One Year from November 1, 1899, to October 31, 1900.—By R. D. Purefoy, H. C. Lloyd, and P. C. Carton.

Four Cases of Laparotomy.—By R. J. Kinkead.

The Journal of Tropical Medicine, March 15, 1901.

Some Notes on Blackwater Fever.—R. U. Moffat holds that blackwater fever is a complication of malaria produced only when the blood glands have lost their normal regenerating power, either through the influence of malaria or any other constitutional cause. It is then caused by a chill acting on the surface of the body when the malarial parasites are in active development, some hours before their sporulation. The effect of the chill is to cause a determination of the parasites to the deeper organs at a time when they should be in the peripheral circulation, and, as a result, sporulation takes place prematurely and there is a sudden death of all parasite-bearing corpuscles. Quinine should be taken as a prophylactic treatment, and even after blackwater fever has appeared the author gives quinine. He also advises free drinking of bland liquids, such as soda water, barley water, etc.; for even if they be vomited, a certain amount will be absorbed and assist elimination and prevent blocking of the kidney tubules. As vomiting is constant the liquid renders it less painful.

A Case of Blackwater Fever.—Dr. Patrick Manson gives a detailed account of his own attack.

The Liverpool School of Tropical Diseases.—Address by Sir William Church.

Beri-Beri in Hong-Kong.—A continued article.

The Birmingham Medical Review, March, 1901.

A Consideration of the Clinical Aspects of Localized Abscess Resulting from Appendicitis.—Leonard Gamgee writes of the abscesses which are likely to form in the midst of adhesions which bind the appendix to other structures. The seat of the abscess varies with the length and direction of the appendix. Its usual position is in the right iliac region, but the pus may run upward and point in the lumbar region, or behind the ascending colon and form a subdiaphragmatic abscess. Luckily, an appendical abscess has a great tendency to point on the surface of the abdomen, but it may burst into the general peritoneal cavity, or into some part of the intestine, or even into the bladder. The author gives the symptoms in the fulminating cases, and in cases of quiet suppuration. He believes that operation should not be delayed. He has operated in twenty-two cases; of these patients twenty recovered and two died.

On the Varieties and Treatment of Prolapse of the Uterus and the Vagina.—Thomas Wilson disapproves of pessaries, and finds that glycerin tampons, made and introduced by the patient every morning, answer far better. They are more cleanly, and they exert on the tissues a tonic and bracing action which helps to prevent further progress of the prolapse. Should the tampons be insufficient to correct the prolapse, the correct indication is to support the pelvic floor on the outside, by a perineal pad, just as one supports any other hernia by a truss. It consists of a hollow india-rubber bag of elongated oval shape, attached by leather straps to a waist-band. When prolapse has become firmly established, operative treatment is clearly indicated. The author gives a list of the various operations suitable for the different varieties of prolapse.

Some Relics of Past Medicine and Surgery in this Part of the Country.—By F. W. Willmore.

Archives Générales de Médecine, March, 1901.

The Genesis of Spina Bifida.—Étienne Rabaud points out the fact that there are two varieties of spina bifida, one consisting of a more or less voluminous pouch, and the second characterized by complete amyelia and an open spinal fissure. The first is the one of interest to the surgeon. The pouch is nothing else than an objective dilatation of the canal of the ependyma, its cavity being directly continuous with the canal. To open this pouch is simply to open the canal of the ependyma and allow of the escape of the spinal fluid. To inject a caustic into the pouch is to inject it into the central nervous system. Neither method should be adopted.

Etiology of Malaria.—M. Vincente says that other agents besides the mosquito play a part in the propagation of malaria. Certain sporiferous parasites of the oleander are known to carry the infection, and it is supposable that many agents of transmission come from plants. The latter mode of infection is less common than that by mosquitos, but on the other hand it can occur at any season, and in winter, when the insect has disappeared, the aspidiotus may become dangerously active if the plants are placed in a hot-house. The latter becomes an artificial marsh, with plants, spores, and insects carrying the spores; together with a deleterious atmosphere favorable to inoculation, multiplication, and infection of the parasite.

Clinical Study of the Acute Broncho-Pulmonary Symptoms Occurring during Malaria.—By J. Crespin and R. Mailfert. A continued article.

Strangulated Hernia in a Child of Sixteen Months.—By G. Michel.

Gastric Toxins.—By E. Cassaët. A continued article.

Varicose Veins.—Cases that may be cured by a thorough and careful operation are: (*a*) Local varix, even of marked prominence, particulary if thrombosis has occurred, either in the thigh or lower leg; (*b*) extensive varix, limited to a single venous stem; (*c*) varicosities which are a bar to passing civil-service, military, or naval examination; (*d*) cases in youth or middle life; (*e*) cases in which the development of the permanent varicosity was at least partially due to more or less removable conditions (flatfoot, garters, etc.).

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL SOCIETY'S ONE HUNDRED AND TWENTY-EIGHTH ANNIVERSARY—SIR W. CHURCH ON THE HOSPITALS COMMISSION—CLINICAL SOCIETY'S DISCUSSION ON TYPHOID IN SOUTH AFRICA—INFLUENZA—SMALLPOX.

LONDON, March 15, 1901.

THE Medical Society of London celebrated its one hundred and twenty-eighth anniversary, on the 8th inst., by a dinner. Sir W. Church was present and replied to the toast of the visitors. He took the opportunity of repudiating Mr. Burdett-Coutts' allegations and the inferences drawn from his statements by some newspapers. As to the statement that the commissioners hurried through their work, Sir William said they did hurry—they landed at Cape Town at 10 A.M. and began their work at 3 P.M., though they had had to find a room, to fix upon what witnesses to hear first, and to make all necessary arrangements. For thirty-four days they worked seven days a week, and the only recreation taken by any of them was to look at the mines of Johannesburg one afternoon after hearing evidence all the morning. Up to the time the army left the Modder for Bloemfontein the care of the sick and wounded had been extraordinarily good, and there never had been a campaign in any country where the arrangements had been so perfect.

The outbreak of fever had to be met by an inadequate staff. No one had an idea of the magnitude of the task, but he was glad to bear witness to the magnificent work of the members of the R.A.M.C. and the great powers of organization many of them showed. Lord Roberts had told them that for fourteen days after he reached Bloemfontein his first thought on waking in the morning was whether he had food enough for the army for that day, and much later the commissariat could keep only twelve hours ahead of the army's needs. In such circumstances the sick suffered certain deprivations. Then too it might be considered what the best civil hospital could do if suddenly overwhelmed with three times the number of patients for which it had provision of any kind.

A discussion on the epidemic of typhoid in South Africa was opened at the Clinical Society on the 8th inst. by Dr. Howard Tooth. His paper embraced his personal experience among the troops, and the origin, dissemination, prevention, and treatment of the disease.

The infection first took place near the Modder River, which was very muddy, the mud being so fine as to clog any filter. Some wells were sunk, but the troops persisted in drinking the river water, which was probably infected by towns above the camp. Bloemfontein was without doubt infected from the Modder camp, for men were taken ill on the march, and many infected at the Modder developed the disease at Bloemfontein. There it rapidly spread—perhaps the Riet River became infected, but other causes than water were present. The virulence of the bacillus is known to be increased by the presence of blood and the toxins of other organisms, even by those normally found in the alimentary canal, as the bacilli coli.

Some of the troops must have been immune, for the bacillus must have had access to their alimentary canal. Such bacilli must be thrown out of the system, or else circulate in the blood without producing the disease. Persons who have had typhoid may retain bacilli in their tissues for years. The water of the wells at Bloemfontein contained a suspicious amount of nitrates, and the water works were at first in the hands of the enemy. But other causes were at work. Sand storms must have been potent agents in dissemination, for at times the food would be covered with sand and dust. Flies, too, though not a serious plague at all times, multiplied rapidly. Personal infection from man to man seemed unavoidable in camp life, and, at the army age, men are specially liable to typhoid. Bad as the epidemic was, Dr. Tooth regarded it as a matter for congratulation that it was not worse. The precautions taken were, boiling and filtering water, sinking wells, disinfection of stools, etc. Out of two hundred and thirty-two cases admitted to the Portland Hospital, fifty had been inoculated, and their death rate was 7.4. Of the non-inoculated typhoid cases the rate was fourteen. The inoculated patients seemed to have milder attacks. Dr. Tooth seemed to think that the degree of reaction to preventive inoculation would be a measure of the natural immunity. His own blood, three months after he recovered from the disease, gave Widal's reaction, which was faintly marked quite lately. An inoculated person may be considered in the state of one who has had the disease, but we must remember a person may have it more than once; so that the toxic saturation point is a variable one. All that can be claimed for inoculation is temporary immunity; but, even so, Dr. Tooth thinks statistics would justify the profession in taking a more decided attitude.

As to treatment, Dr. Tooth made some important observations. He protested against leaving it too much to nurses. There were worse places than a comfortable tent in the open air, he said, and food might often be given more freely than is the custom; sterilized milk is expensive, condensed not very nutritious; he had given finely minced meat when the tongue was clean; the growth of bacilli is favored by the presence of other bacteria, and these again by undigested food; dry, brown tongue, disinclination for food, and frequent stools indicate most careful dieting; stimulants are useful only when the pulse is weak and rapid; phenacetin relieves headache but causes profuse sweating, so atropine should be added; the care of the mouth and tongue is important; pain in taking food may produce disinclination. For hemorrhage he used turpentine, hamamelis, and digitalis. From perforation few recovered; some cases were treated surgically, but without success.

Surgeon-General Jameson, director-general of the medical department, said that from year to year an epidemic of typhoid occurred at Ladysmith and Pietermaritzburg, and on the outbreak of the war he saw that such an event stared them in the face. He therefore had instructions drawn up to guide the medical officers, and he did not think anything needed to be added to his instructions.

It was unfortunate that the sanitary officer had been abolished in the field army, and he had, on his own responsibility, appointed Captain Hughes and equipped him with portable chemical and bacteriological laboratories and sent him to watch the epidemic anticipated. Sir R. Buller put Captain Hughes on his personal staff, but unhappily he was killed at Colenso—a national calamity. One of the chief difficulties to meet was certainly the soldiers' drinking whatever came in their way, of which he had had personal experience at Quetta and Alexandria. He described the method adopted by the Americans to meet the danger of the excreta.

Professor Wright spoke on inoculation. He said those who had severe reaction did not do so well as those who had smaller doses. A man who had had an attack of the disease was known to be more immune than one who had not. Every one after typhoid had good Widal's reaction, and in testing the blood we should get an equal reaction. Some persons recovered with reduced bactericidal power of the blood; hence came relapses. People with slight bactericidal power were more liable to relapses. He mentioned the case of an officer who had had two inoculations and four attacks in two years. It was necessary to bring the blood into the condition in which it was in patients who had recovered. The preventive serum should be inoculated twice with a sufficient interval for full recovery. Some statistics were given.

Sir Dyce Duckworth paid a high tribute to Professor Wright's modesty and caution, and held that the process should be tried by the civil community.

Surgeon-Major W. G. Macpherson said Dr. Tooth had shown the truth of all they believed before the campaign. The reason armies suffered so severely was that many men were dumped down on undrained and unsuitable places. The Americans had concluded that a system of water-carried drainage was the best preventive. He described the plan they had adopted and said an effort was being made to follow it in our army. As to flies, instructions were given for destroying their breeding-places. Deep trenches for excreta were better than shallow, and tube drainage was better than buckets. The discussion was then adjourned.

Influenza is on the increase in London. In the last four weeks the deaths registered from it were 16, 32, 35, and 39. The deaths from all respiratory diseases during the same weeks were 430, 493, 501, and 463. The last number is 97 below the corrected average.

Smallpox is still serious at Glasgow; the deaths for the last four weeks being 20, 15, 12, 20. Great efforts are being made to push vaccination and revaccination. A house-to-house canvass is being made with the offer to vaccinate all who will submit to the protection.

ENLARGEMENT OF THE SUBLINGUAL VEINS IN INFANTILE MYXŒDEMA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Recently I observed in a case of sporadic cretinism, or infantile myxœdema, a condition which, to my knowledge, has not been described; namely, a marked dilatation of the veins on the under surface of the tongue, amounting, in fact, to true varicosities, particularly when the infant would cry.

It seems to me that this condition is but the result of pressure excited by the hypertrophic tongue, thus render-

ing the return circulation very inactive. So great did the dilatation appear at the crying periods that one could not fail to be impressed with the safety in this case of delayed dentition. It can easily be imagined that during a severe paroxysm such a tense and dilated vein might be ruptured by a sharp incisor. Though not of great practical importance, it is a fact which appears to me worthy of clinical note.

I might add that, since the infant has been medicated with increasing doses of thyroid extract, this venous dilatation has gradually subsided, and there has been improvement of the general condition and diminution in the size of the tongue.

JACOB SOBEL, M.D.

1828 MADISON AVENUE, NEW YORK CITY.

SHOULD LEPERS MARRY?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: For my part, I do not think it advisable to allow lepers to marry, leprosy being a bacillary disease: the fewer contacts between the diseased and healthy populations that are permitted the less danger of contagion there would be. Unless a leper is already married, when he becomes a leper he should not be allowed marital intercourse with a healthy person, because he might contaminate his wife and children, if any should be produced; and he should not marry a leper because the thought is monstrous —as monstrous as for the tuberculous or syphilitic to marry. The old marital law of Japan prohibited marriage with a leper, and the divorce law recognized as a reason for the annulment of the relation even "the tendency to leprosy discovered too late." Moreover, the greatest obstacle to leprous sanitation in Japan has been the superstition that if leprosy appeared in a family, and any one should divulge the fact, and thus injure that house's reputation, retribution would surely overtake the informant. Hence they pity the family's misfortune, and keep its secret. This tradition doubtless has come to Japan through China and Corea from India. In Japan, as in India, lepers in their outeast villages have always propagated children among themselves. Thus the spread of the disease from parent to child has been enormous. The traditional government of the leprous population by the Buddhist hierarchy has been outside the statutory regulations, and the Buddhist priests have allowed marriages between leprous men and leprous women "for their moral good and happiness." In this way non-leprous children have constituted new foci for the germs of the disease throughout the empire. For by their year of contact with leprous parents in leprous villages they had been, as it was discovered afterward, inoculated with the disease. They were the germ carriers. Moreover, the bacillus is frequently found in the leper's testicles; it has also been found in the sperm, although the male germ, accompanied with a bacillary element, as in syphilis, has only few chances of life. In the uteroplacental transmission of leprous contagion there may be interruption of the development and death of the fœtus before term, or non-viability at birth, or birth at full term with accidents. In the first months, or first year, of life without a recognition of the disease, Zambaco Pasha claims to have observed the first two cases; he found nine children of lepers, before term, badly developed, very weak, with discolored deep-red skin. The children died a few days or weeks after their birth. The third case was not found by Zambaco, by Danielsen, or by Boeck, who saw only leper children live or seven months after birth. In "Kaposi Notes," Besnier thinks that the probability of leprous inheritance is weak even when father and mother are lepers. The heredity of the disease is not fatal, and children of lepers might be isolated and taken out of the country as soon as born. This would be the surest and best means of extinguishing leprosy. This, of course, would take from the leper the moral good of his marriage. Norway has had to do it, to cleanse herself of leprosy. Her children and grandchildren of lepers were shipped to the United States. Thus, the spread of the disease was checked. England, justifying herself by an assumed belief in non-contagion, is doing the same thing with India; 263,000 Hindus, more or less related to lepers, were shipped to French Mauritius; 118,000 were sent to British Guiana, 83,000 to Trinidad, and 14,000 to Jamaica. Bevan Rabe found in Trinidad 214 Hindu lepers. To-day Great Britain is shipping Hindus, inoculated with leprosy, to British East Africa, Uganda, and the Upper Nile.

Dr. Lucio admits heredity of leprosy, and considers the disease a family disease. Bosnet calls it heredocontagious. Hansen says that leprosy is a family disease, "not because it is hereditary, but because it is contagious and exists in the families where contagion is most easily produced." Zambaco also does not believe in heredity. "In the largest number of cases I have observed," he says, "leprosy was spontaneous, accidental, without heredity. Virchow believes in the heredity of the predisposition to leprosy but not in a congenital disease. The investigations of Boeck and Bidencop proved that the disease has indicated itself in ascendant line only in the fourth part of the Norwegian lepers. Von Souneron found in Madras only two cases of heredity in thirty-one cases of leprosy. Leloir does not take much stock, either, in the heredity doctrine. In his statistics, in one hundred and seven cases of leprosy there was demonstrated heredity in only forty-seven. He says the children who owe their life to a leper, male or female, or to the union of two lepers, are not always affected with the disease, especially if they part from their parents, and betake them to a land where there is no leprosy.

Leprosy begins generally between ten and twenty-five years, seldom before three and five years, more rarely at one or two, or at an advanced year like seventy.

The heredity of lepers has not been proved, and if it exists really, either in the direct form or as predisposition, this does not account for the greatest number of the cases observed. The rapid propagation of leprosy in leper countries cannot be explained by heredity. Perhaps the instances of family leprosies, adduced in favor of heredity, constitute only examples of family contagion, as believe Schilling, Drognat, Landré, Hansen, Neisser, etc.

Let us not forget that the period of incubation is unknown and sometimes long. Landré has known of fourteen years' incubation. To prove heredity it is not sufficient to quote families in which several members are lepers, because with the same criterium we could quote as hereditary such diseases as are acquired in a family by contagion, like scarlet fever, smallpox, etc.

In the statistics of Danielsen and Boeck, in sixty-eight anæsthetic lepers, leprosy was indicated, in ascendants, in fifty-eight cases; in two hundred and thirteen tubercular, there was heredity indicated in one hundred and eighty-nine, and for the others it developed spontaneously.

It results that it might be, strictly speaking, admitted that leprosy can be transmitted by heredity, considering, as I have said, heredity as heredocontagion. The greatest part of the cases of heredity indicated are simply cases of contagion. Children of lepers must leave their parents and their country as quickly as possible.

In conclusion, I beg to inform Dr. Carleton, of Sabathu Leper Asylum, India, that American physicians will always be found able to instruct Great Britain in the matter of her vast Indian leper problem.

ALBERT S. ASHMEAD, M.D.

NEW YORK, March 26, 1901.

LETTER FROM AUSTRALIA.

(From Our Special Correspondent.)

THE PLAGUE AND HEALTH BOARD REFORMS—ABUSE OF MEDICAL CHARITY—PRESCRIBING CHEMISTS—THE BRANCH BRITISH MEDICAL ASSOCIATION MEETINGS.

QUEENSLAND, AUSTRALIA, February 15, 1901.

THE matter with most small communities is that they consist of a number of individuals, each of whom knows more about everything than does any one else. The special knowledge of a special class is of little value to such people since they are unable to comprehend its existence; for them, indeed it does not exist. That the communities in Queensland towns are of such a kind has been well known during the recent plague scare which visited the shores of this state, veritably the shores, since no cases of pestis occurred inland. One is pretty safe in asserting that the majority of the freely educated inhabitants are still of the opinion that it was not plague, but something else which the doctors called plague for some reason of their own. ("D——n their ignorance!" as Dr. Johnson would have said.) Now that it has gone, never, let us hope, to return, the bitternesses engendered by the stubborn and stupid obstinacy of the ignorant may be "regulated to the lumbago of the past," but it has taught its lesson and brought its results. One of these is the new health act and the appointment of Dr. S. S. Ham as commissioner of health, with the reconstitution of the central board of health which becomes merely an advisory board to the commissioner. The latter is given great powers, and will doubtless institute many accessory reforms. He comes to Queensland with a good record.

Dr. Halford has been appointed health officer to the "joint epidemic board." He is a young and enthusiastic physician and should fill the office well. Previously to his appointment the city of Brisbane was served by a general practitioner, who received an income of £20 a year for his services!

The appointment of a medical man as inspector of charitable institutions (Dr. Hare, author of a valuable work on the cold-bath treatment of typhoid fever) promised to pro-

duce excellent results in the direction of the reduction of the abuse of charities by the well-to-do. So far, however, there do not appear to be any great results from the appointment, though it is possible that the inspector is doing more work than comes under the notice of the profession.

The record of the Queensland branch of the British Medical Association for 1900, represented by the report of the council, is a good solid one. A large number of meetings are held and much work is done. It is a matter for regret that the efforts of the branch were not successful against the prescribing chemists who succeeded in blocking the proposed new medical bill. Among the papers read at the branch meetings, one by Dr. Francis, vice-president, on intranasal pressure as a cause of headaches, and notes by the same member on a case of emphysematous otitis due to the presence of the bacillus aerogenes capsulatus (the first recorded case) were of particular interest, as also were some notes on plague by Dr. Turner, and the non-operative treatment of some forms of tubal disease by Dr. Hawkes. The branch practically represents the progression in Queensland, since its fusion with the older Queensland Medical Society, and promises to be a strong, united, and useful body.

I hope in a future letter to write in some detail of the hospitals of Queensland, or, perhaps, of those only with which I am personally acquainted.

Reviews and Notices.

Essentials of Histology. By Louis Leroy, B.S., M.D. Philadelphia: W. B. Saunders & Co. 1900.

A series of practical questions and answers, amply illustrated; will serve the purpose of the author.

Les Maladies Qu'on Soigne. Par A. Berck. Paris: F. Calot.

This is a small but very interesting surgical treatise. It comprises chapters on the surgical management of cold abscesses, adenitis, osteitis, coxalgia, Pott's disease, scoliosis, and congenital dislocation of the hip-joint.

Laboratory Directions for Beginners in Bacteriology. By Veramis A. Moore, M.D. Boston: Ginn & Co. 1900.

This little book is intended to serve as a guide to workers or beginners in bacteriology. It is very rudimentary.

Perfect Eyes: A Complete and Comprehensive Treatise on the Organ of Vision. With 39 colored plates and 40 others in the text. Sixth edition. New York: Benjamin F. Stephens.

"Perfect Eyes" is in its sixth edition. It appears without a preface or index. The book contains seventy-one pages, is written in a popular vein, and is very profusely illustrated. Technical terms are used but little. Semeiology is indulged in. Many inaccuracies in statement are met with in the text. The purpose of the book appears to be the advocacy of manipulation and local massage for the cure of all of the congenital and acquired abnormal conditions of the eyes. It really belongs in the category of "quack" literature, and is full of misinformation for those whom it is intended to reach.

Comfort and Exercise: an Essay toward Normal Conduct. By Mary Perry King. Boston: Small, Maynard & Co. 1900.

Comfort, the writer of this interesting little book defines as the right adjustment between self and circumstance, and she discusses the means best adapted to attain it in relation to education, occupation, home life, social life, and dress. In all these relations the essential of comfort is harmony—the natural fitting together and interplay of the intellectual, the spiritual, and the physical. It is especially with the latter that the author has to do here, the greater part of her work being devoted to the subjects of dress and exercise. The relation of apparel to morals must be more intimate than we thought if the writer is correct in her statement that "the warped and unintelligent characters of many men and women, much of the inhumane pettiness, bigotry, and spite, are due quite as much to the incessant and tyrannous irritation of clothes, as to any inherited depravity." The benefits of well-conducted gymnastic exercises are well set forth in the final chapters in which the right theory of exercise is demonstrated and its practice illustrated in the description of the ideal gymnasium. The essay is charmingly written, though the writer's earnestness leads her at times to the use of English which is almost too masculine in its vigor, and its perusal will entertain as well as instruct. We are sure the reforms urged in the book would benefit the health and increase the personal comfort of Woman—with a big W—but would it make the little women we know and love more charming and more lovable than they already are? Perhaps, but we somehow shrink from the thought of radically changing them, lest there be some shifting of "the adjustment between self and circumstance."

The Art of Breathing as the Basis of Tone Production. By Leo Kofler, Organist and Choirmaster of St. Paul's Chapel, Trinity Parish. Fifth revised edition. New York: Edgar S. Werner Publishing and Supply Co. 1900.

This book is of convenient size and embraces two hundred and seventy-six pages of rather closely printed text. A few illustrations appear in the body of the work. The writer, who is an enthusiast on what he terms "the art of breathing," has divided his work into three parts, the first of which is devoted to "items of interest to the reader," and contains a short biographical sketch of the author. The second part treats of the "theory of breathing," the third part deals with the "laws of tone production." In the sixteen chapters into which the three parts are subdivided, breathing gymnastics, tone production, the practice of phonetics, and methods of correcting faulty and defective articulation are fully considered. The work is based on the experience and observation of the author and on a knowledge, perhaps sufficiently complete, of the anatomy and physiology of the thorax and tone-producing organs. It is rather prolix, but contains much that is of value to those for whom it was written.

A Treatise on Diseases of the Nose and Throat. By Ernest L. Shurly, M.D., Vice-President and Professor of Laryngology and Clinical Medicine, Detroit College of Medicine; Laryngologist and Late Chief of Staff, Harper Hospital, etc. Illustrated. New York: D. Appleton & Co. 1900.

This book, which is well printed and well bound, is one of seven hundred and forty-four pages; it contains seven hundred and eighteen cuts in the text and is embellished by six colored plates, each comprising a number of figures. A very full formulary is added. A consideration of the anatomy and physiology of the upper air passages is found in the first chapter. A chapter devoted to methods of examination follows, after which the various conditions and diseases of the nose and throat are discussed in logical order. The subject is treated in a modest, able, energetic, systematic, and sufficiently exhaustive manner. The diction is smooth and pleasing, the language simple and direct. A full acquaintance with the past and current literature on the subject is evidenced and the text is well up to date. Illustrations are found wherever they can be of service to elucidate the text, and nothing pertaining to this special branch of medicine has been passed without having been given careful consideration. One of the valuable features of the work is the discriminate but full consideration of therapeutic measures in connection with all of the various diseases discussed. This work deserves a place in the library of every medical man who has anything to do with the diseases of which it treats. It cannot fail to attain a large circulation.

Infant Feeding in its Relation to Health and Disease. By Louis Fischer, M.D., Attending Physician to Children's Service, New York German Poliklinik, formerly Instructor in Diseases of Children in the New York Post-Graduate Medical School and Hospital, etc. 12mo, pp. 350. Philadelphia and Chicago: F. A. Davis Co. 1901.

In these days, when there is so much discussion on infant feeding, it is a relief to meet with a thoroughly scientific work on the subject, dealing with broad general principles and applying them to the wants of all. The subject is compassed in a thoroughly practical way, not only on a clinical but a pathological and bacteriological basis. Breast feeding, hand feeding, and bottle feeding are discussed in all their bearings and indications. Commencing at the natural beginning, the anatomy and physiology of the gastro-intestinal tract are clearly considered. In this connection the original studies of relative gastric capacity from birth to one year of age are interesting and instructive as preparing the way for the general description of the processes of fermentation and absorption. The chemical ingredients of milk—fat, sugar, proteids, salts, and water—are exhaustively treated in their turn in connection with the actions of the common intestinal bacteria and with original drawing of colostrum milk. How to determine the nutritive value of breast milk, how to feed a baby at the breast, how to feed on mixed food, the diet of nursing women, and the indication and counterindication of drugs through the

nurse on the child are very clearly presented. The importance of the proper weaning of the infant is manifested by many practical details of management. The main interest in the work centres on the use of raw milk as the foundation of proper artificial infant feeding. The real emphasis is on pure raw milk. The author truly says: "If greater attention were bestowed on the condition of the cow, her udder, the stable, the bucket, and the milker's hands, then less sterilization and less pasteurization would be necessary." One of the fruitful sources of rickets and scurvy is due to lack of attention to the raw-milk question. As the design of the author is to teach the general practitioner how to feed infants away from laboratories and beyond the reach of patented foods, he gives the most elaborate and detailed directions for what he styles the "home modification of milk." The various digestive disorders from improper feeding are treated very fully and practically and form one of the many valuable features of the work. The dietary, giving the details for preparing the various cereals as diluents, cannot fail to find favor with the careful physician who desires accurate scientific facts and common-sense application of them. The work is profusely illustrated and contains some admirable and striking representations of different forms of rachitis and marasmus. Altogether the work is a model of its kind and cannot fail to appeal to the practitioner who desires accurate scientific data on such matters as bear on the proper care of the infant during the most trying period of its otherwise helpless condition.

A Manual of Otology. By Gorham Bacon, A.B., M.D., Professor of Otology in Cornell University Medical College, New York; Aural Surgeon New York Eye and Ear Infirmary. With an Introductory Chapter by Clarence John Blake, M.D., Professor of Otology in Harvard University. Second edition, revised and enlarged. With 114 illustrations and 3 plates. New York and Philadelphia: Lea Brothers & Co., 1900.

This excellent manual has reached its second edition. It has been thoroughly revised and brought up to date. The volume, which contains four hundred and twenty-two pages, is of convenient size, abundantly illustrated, and is embellished by two colored plates. It is beautifully printed and well bound. The introductory chapter by Dr. Clarence J. Blake, of Boston, is a very valuable feature of the book. The subject matter has been carefully considered and ably presented. Few books on diseases of the ear are as well adapted as this for the use of students and the general practitioner.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 25, 1901.

George B. Fowler, M.D., President.

The Importance of Aseptic Vaccination.—Dr. Wilhelm Karl Kubin read a paper with this title (see page 524).

Dr. John H. Huddleston said that a large proportion of the bad results reported by the British commission were nothing more than cellulitis. The sepsis observed in most vaccination cases was generally conceded to have originated after the performance of vaccination. It should be remembered that the possibility of sepsis increased very rapidly with the size of the area scarified. If the scarification was only a pin point in size, the resulting vaccination vesicle would still be a circle of considerable size. If the large scarifications formerly employed were used now with the active glycerinated lymph, the resulting vesicle would be extremely large. The rule should be to make the area as small as it was possible to do. With a scarification of one-eighth of an inch, post-vaccinal sepsis would be extremely rare. If a shield could be contrived which would keep its place, protect the wound, and not move up and down, it would be a most desirable thing; but certainly most of the shields now on the market did not meet these requirements, and were, on the whole, dangerous. The worst arms that he had seen recently had been almost uniformly those on which shields had been used. A loose shield moved up and down, broke the vesicle, and distributed the lymph. If, on the other hand, the shield were fixed so tightly to the arm as to prevent its moving, the tissues of the arm adjacent to the vaccination would become swollen and less resistant to infection. Most of the vaccines on the market had been found practically sterile, and hence the large number of very sore vaccinated arms still seen must be attributed to infection occurring after vaccination.

Dr. George H. Fox said that one should be most careful to adopt aseptic measures in vaccination if only because every severely sore arm became an argument to be used by the opponents of vaccination. In his experience many of the sore arms had resulted from the use of the wire cages and the stiff pasteboards so generally sold in drug stores. These became veritable hot-houses and culture beds for germs, and the circulation of the surrounding tissues was impaired. He did not quite understand why most physicians were so careful not to disturb the vaccine vesicle, for this seemed to be a matter of importance only when one desired to study the formation of the vesicle or the stages of vaccination. He suggested that it might be better to treat the vaccinal lesions just as one would treat the lesion of contagious impetigo, *i.e.*, by removing the crusts and applying an ointment of ten grains of the ammoniated mercury in one ounce of cold cream or zinc ointment. He was inclined to think this would produce less irritation and inflammation than the ordinary mode of treatment.

Dr. Charles W. Allen said that he had seen so much harm from shields that he now did not employ them, and hence, if he tried Dr. Kubin's shield, it would be only in an experimental way. Strong antiseptics should not be used on the arm prior to performing vaccination. In about ten thousand cases of skin disease, seen in the past two years, he had noted twenty-eight more or less generalized eruptions following vaccination, and also a number of accidental vaccinations. During the past year he had seen a good many deep and slowly healing ulcers after vaccination. He had attributed these largely to the use of poor vaccine, and this view had been strengthened by the fact that more recently he had observed as many, if not more cases, and yet there had been a much smaller proportion of these bad results. From 1897 to 1899 four thousand one hundred and sixty children had been vaccinated at the Good Samaritan Dispensary. Of these, fourteen per cent. had returned with some abnormal condition, and fourteen per cent. of these had exhibited eruptions, even generalized vaccinia—the existence of which had been denied by some observers. It was most important to remember that the very act of vaccination precipitated various eruptions, including that of syphilis and of the various exanthemata. His own practice was to paint a three-per-cent. solution of methylene blue in collodion, in a ring around the vaccinated area, and to cover this with cotton. When he desired to inspect the vaccination, it was necessary to remove only the centre and replace the dressing. Such a dressing could not possibly be displaced, and it answered the purpose of the usual vaccination shields without their disadvantages. He had been much interested in Dr. Fox's suggestion concerning the treatment of the vaccination vesicle as one would a case of contagious impetigo. He believed this would give just as good protection from smallpox as if the process had gone on to the formation of an ulcer.

Dr. A. Ernest Gallant said that from 1887 to 1896 there had been about one thousand three hundred cases of infection after vaccination observed at the Good Samaritan Dispensary. They represented,

of course, all grades of severity of infection. The moderately severe ones had been treated with a dressing of five per cent. balsam of Peru in castor oil. When there were much redness and swelling, the application of ichthyol would cause a speedy subsidence of these signs of inflammation and infection.

Dr. Kubin, in closing the discussion, said that he could not see the reason for disturbing the pustule. It was a self-limited process, and when infection did not occur, interference did not seem to be called for.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, March 19, 1900.

E. Franklin Smith, M.D., Chairman.

Points Connected with the General Etiology and Pathogenesis of Diabetes Mellitus.—Dr. Heinrich Stern read this paper. He said that it might appear a paradox, but was a fact that in the United States the mortality statistics afforded us the most reliable method of obtaining certain general etiological data. He had studied the mortality statistics pertaining to diabetes mellitus of New York City for eleven years (1889–99 inclusive), and had derived the following data therefrom:

Sex.—Of 1,867 deaths from diabetes mellitus, 931, or about 50 per cent., occurred in females. This proportion differed a good deal from the supposition that the malady was much more fatal in males than in females. Former mortality reports had shown that from two to two and one-half times more men succumbed to the affection than women. It was but consequential to assume that the death rate for diabetes mellitus stood in direct proportion to the frequency of the disease itself, and that in New York City about an equal number of both sexes were affected with it.

Infantile Diabetes.—He had found thirteen instances in which the disease terminated fatally below the fifteenth year of life. The total mortality from diabetes in infancy and early adolescence being 79, formed about 4.25 per cent. of the total deaths from this disease during the eleven years.

Race.—Of the fifteen instances of death from diabetes which had occurred among the colored population of New York City between 1889 and 1899, 9 were in males and 6 in females. Hebrews undoubtedly were more commonly affected with chronic glycosuria than was the nation among whom they dwelt: out of a total of 202 deaths in 1899, 54, or about 25 per cent. had occurred in Jews. Of those, 21 were males and 33 females. Among the Irish population 37 had succumbed to diabetes in 1899. Taking the Irish as a race—as the author had done with the Jews—and adding those who were born outside of Ireland of Irish parentage, or who were of Irish descent, one had a total mortality of at least 51—22 males and 29 females. This figure also formed over 25 per cent. of the total mortality from diabetes mellitus. The cardinal predisposing cause in the production of the diabetic state, in Hebrews and Irish, the author thought, was the breeding in and in, to which, in a very pronounced degree, both races still adhered.

Social Condition.—Diabetes mellitus was not a special visitation upon the rich, as was commonly supposed. Among the 202 males who had died from diabetes in 1899, 66 at least were working for a livelihood, or were dependent upon others, and lived in tenement houses.

Clinical Varieties.—For clinical purposes the various glycosurias might be ascribed to one or more of the following causes: (1) Excessive ingestion of glucose or alimentary glycosuria; (2) Diminution or functional disturbance, or excessive or abnormal disintegration of erythrocytes: glycosurias following the introduction of poisons and toxins, or the perverted function or removal of certain glands and organs—hæmatogenic glycosuria; (3) Traumatism—neurogenic glycosuria; (4) Interference with the glycogenic function of the liver to the extent that the ingested carbohydrates were not utilized normally—common or hepatogenic diabetes; (5) A general protoplasmic deterioration and plasmolysis—diabetic deterioration.

The primary cause of all hyperglycæmic conditions, excepting the alimentary form, seemed to be one and the same. The speaker assumed that the primary stimulus of hyperglycæmia acted by the medium of the blood; he considered only the hæmatogenic form, and the most typical of all diabetic conditions—the diabetic deterioration.

Hæmatogenic Glycosuria and Diabetes.—Bremer's method of diagnosticating diabetes from a drop of blood was not very likely ever to supplant the more approved tests for glycosuria; it had, however, drawn attention to a hitherto unknown factor in hyperglycæmia—the erythrocytes of diabetic blood did not stain with certain aniline dyes as did those of normal blood. Bremer found that the non-coloration did not depend on the presence of dextrose, as it did not ensue in artificially saccharated healthy blood on the application of the eosin-methylene-blue solution. He concluded that there must be a foreign substance in the diabetic erythrocytes, which called forth the unusual phenomenon. The reaction of diabetic blood upon certain aniline color stuffs, according to the essayist, seemed to be a purely chemical process. This interaction might be due to the presence of an abnormal element in, or the absence of a normal substance from, the diabetic blood, or to both eventual factors together. As early as 1896, the author had approached this subject. At that time he was inclined to Ebstein's theory, which supposed that the general oxidizing qualities of the diabetic organism were more or less impaired—an assumption not borne out by modern investigations. He inferred that there must be a certain connection between Bremer's phenomenon and the oxygen-carrying property of the diabetic red blood corpuscle. He considered carbon monoxide of catabolic origin the replacing factor of oxygen in the hæmoglobin. He had, however, considered himself that the changes in the cellular substance of the diabetic red blood corpuscle were neither the direct nor the indirect result of CO intervention. The almost characteristic behavior of the diabetic erythrocytes must be due to another factor, which might be either the result or the cause of the diabetic condition. This abnormal element was presumably of autochthonous formation, perhaps, though it took its origin from exogenetic influences. If the foreign substance had arisen from within the organism, it was either enterogenous or histogenetic. It did not seem to be due to a retention anomaly, as carbonæmia and carbon-oxidæmia *per se* failed to reduce the aniline-dye stains. If the substance were derived by resorption from the gastro-intestinal canal, it could not become an almost permanent factor in the blood, as this would presuppose a long-continued, uninterrupted absorption of the products of intestinal hyperfermentation and putrefaction, a condition hardly ever prevailing, and, in the author's experience, not frequent in diabetes. We had, therefore, to regard the substance (not considering at this moment its possible autogenesis) as a product of abnormal cell and organ activity or disintegration. Thus the foreign substance, whether it originated by perverted plasmolytic or nucleolytic processes, or by anomalies of internal secretions,

might safely be classified among the toxin principles. The possibility of an ectosystemic origin of the foreign substance deserved some attention. A number of observers had found the appearance of diabetes in formerly healthy persons after they had come into contact with diabetics. The transmissibility of the affection seems feasible, although no convincing proof had been given for it. One could surmise that the abnormal blood constituent represented the metabolic products of a specific bacterium, and that the potency of this toxin gave rise to the glycosuric phenomenon.

The Diabetic Deterioration.—A number of writers distinguished between a mild and a grave form of diabetes, but they contended that both were manifestations —differing in degree only—of the same directly underlying pathological condition. Seegen had been the first to recognize two distinct and independent clinical types of the diabetic affection. The present author had described a third clinical form of diabetes—the diabetic deterioration. These three clinical varieties of diabetes, emanating respectively from three distinct direct causes, seemed, however, to be but the consequence of one and the same fundamental disturbance. In the first form, the glycosuria disappeared after complete or partial exclusion of carbohydrates. The excreted dextrose was due to deficient glycolysis. In the second form, the glycosuria persisted after the complete exclusion of carbohydrates. The excreted glucose was due to proteolysis. In the third form, the continued excretion of dextrose concurred with larger amounts of nitrogen egested than were introduced with the nutriment. The excreted dextrose was due to plasmolysis. This third form of diabetes seemed to be the manifestation of a specific plasmolytic process.

In the healthy organism a dextrose-resembling substance might be normally yielded by plasmolysis, which, after it had undergone succeeding changes, was ultimately disposed of as CO_2. However, the production by plasmolysis of dextrose, or of its precursor, appeared to be an abnormal catabolic process, which caused permanent disintegration of the tissue protoplasm. This specific dissimilation of the living protoplasm, induced perhaps by the erythrocytic foreign element, was a limited hemimetabolic metamorphosis, so to speak, and bore the character of a deterioration; that is, the protoplasm might retain its appearance and might continue to exist, although it had permanently lost its molecular integrity. This plasmolytic dextrose-carbamid-yielding process the author had designated as diabetic deterioration—in other words, diabetic deterioration was a more or less limited molecular disintegration of plasmotic tissue substance into a carbohydrate body and a non-colloid nitrogenous compound. A logical and concomitant phenomenon of the hyperexcretion of nitrogen was the progressive inanition of the patient affected with the disease. The glycosuria was persistent, but its intensity did not seem to reflect the progress or the exact stadium of the disease.

Diagnosis and Prognosis of Diabetes.—Dr. Henry S. Stark was the author of this paper (see page 535).

Diabetes in Children.—Dr. Henry Dwight Chapin read this paper. He said that diabetes in children was a very rare disease, but Gerhardt had succeeded in collecting one hundred and eleven cases in children varying from eleven months to sixteen years of age. He had himself seen only two cases. The first one of these was in a boy of four years who had had more or less fever, associated with rapid loss of strength and the passage of from one hundred and five to one hundred and ten ounces of urine daily. The other child had presented an almost marvellously rapid emaciation, and the urine had contained about five per cent. of sugar. Both cases had proved rapidly fatal. The most marked symptom of the disease in childhood was rapid emaciation.

The Nervous System in Diabetes.—Dr. Pearce Bailey said that in the fifty years that had elapsed since the classical experiments of Claude Bernard the evidence in favor of the nervous system being the origin of diabetes had been weakened. All experimental glycosuria was temporary. The result of pancreatic extirpation had been uniformly fatal, and permanent glycosuria, following experiments on the pancreas, had been observed only when the pancreas had been severed from all connection with the nervous system. Traumatism was an important factor. Thus, in a series of two hundred and twelve head injuries, glycosuria had been observed in twenty, which included simple scalp wounds as well as fracture of the skull. Cases were on record to show that diabetes resulted from general traumatism, the latter acting probably directly upon the processes of metabolism. In many diseases of the nervous system diabetes was mentioned as a complication, but in the large experience at the Vanderbilt Clinic diabetes had been a rare complication. Of the affections in which it had been most commonly found were general paresis, multiple sclerosis, tabes, myelitis, neurasthenia, paralysis agitans, and hysteria. The speaker thought the cause of diabetes would probably be found in the glands rather than in the nervous system. Diabetic neuralgia might affect any nerve, but it very commonly affected the sciatic. Neuritis was common in diabetes, and the urine should be examined in every case of neuritis.

Cutaneous Complications in Diabetes.—Dr. S. Sherwell read this paper. He said that prominent among those cutaneous manifestations observed in connection with diabetes was generalized scleroderma of the functional variety. There was usually a distinct general pruritus and a peculiar "ribbed" and very characteristic appearance of the mucous membrane of the mouth. Eczematous manifestations in diabetes were quite common, and the intensity of the pruritus should lead to an examination of the urine, not only that voided in the morning, but also that from other hours of the day. Cleanliness and antiparasitic lotions would be found more beneficial than the ointments ordinarily prescribed. A 1 : 1,000 solution of the bichloride of mercury had proved very useful in his hands. Furuncles of the neck and of the gluteal region were also frequently observed in diabetics. Erythematous lesions, such as erysipelas and gangrene, were common in diabetes. The only cases of erysipelas of the mouth and upper air passages that he had seen had been in diabetic subjects. A form of vesicular and bullous disease—the so-called dermatitis herpetiformis—occurred in connection with diabetes. Another cutaneous manifestation of considerable interest was a tumor formation called xanthoma diabeticorum. He was also disposed to think that blastomycetic dermatitis might be included in this class.

Ocular Manifestations in Diabetes.—Dr. Neil J. Hepburn read this paper. He said that the most common changes in the eye seen in diabetes were cataract, retinitis, oculomotor paralysis, iritis, paralysis of accommodation, keratitis, hemianopsia, glaucoma, and detachment of the retina. The diabetic cataract was most often observed in young people. The retinitis was apt to be associated with punctate hemorrhages. The oculomotor paralyses were usually incomplete. The recurrence of stye in cases in which the refraction had been corrected should lead one to examine the urine for sugar.

Diabetes Mellitus in Surgery.—Dr. Robert T. Morris read this paper. He said that formerly surgeons looked upon diabetics as entirely unfit for surgical operations, but this opinion had been very greatly modified in recent times. The blood, when loaded

with sugar, abstracted moisture from the tissues, rendering them dry, and thus interfering with nutrition and with the repair of wounds. It was probable also that the alexins were not properly formed with the toxins to combat the occurrence of infection. Whether this was true or not, it was a well-known fact that the surgeon must be especially careful to guard against infection when operating upon diabetics. The sugar in the blood probably also interfered with repair by rendering the blood serum a good culture medium for bacteria. Gangrene certainly occurred in diabetics, but much less frequently than formerly. He thought it probable that the gangrene in these cases was the result of choking of the lymph channels by leucocytes, which were unable to do their work because of the lack of moisture. Diabetics were apt to have irritable kidneys, and the use of ether as an anæsthetic might increase their irritability to a dangerous degree. For this reason he favored the employment of nitrous oxide preliminarily to the ether. In many cases of traumatic glycosuria there was a disappearance of the sugar from the urine after a time, though the patient still suffered from polyuria.

Treatment of Diabetes Mellitus.—Dr. Abraham Mayer was the author of this paper. He said that the treatment naturally resolved itself into dietetic, hygienic, and medicinal. He was accustomed to divide his cases into the mild and severe forms. By the mild form was understood that form in which, by the removal of the carbohydrate food, the glycosuria was nearly or completely checked. It was a great error to exclude carbohydrates entirely from the food of diabetics except for the purpose of diagnosis or at the beginning of treatment. When the small quantity of sugar persisted along with such diet, it would be necessary greatly to reduce the proteids. Many diabetics would assimilate a large quantity of lactose without showing any increase in the sugar in the urine—in fact, milk formed a prominent part of the diet in his diabetic patients. The arrangement of the diet for diabetics in private practice was not an easy matter. The food should be adjusted to the weight and sex of the patient, and would vary, depending on whether or not he was engaged in a laborious occupation. The following dietaries indicated in a general way what should be the aim of the physician in this respect:

Mild Diet.—For an individual weighing 70 kgm.: 8 A.M., a cup of coffee and milk with saccharin; 25 gm. white bread and butter; 50 gm. of broiled ham. 10 A.M., one cup of bouillon. 1 P.M., six oysters or clams on the shell; soup with asparagus; 200 gm. of baked fish; lettuce; 100 gm. of roast veal; spinach; 20 gm. of cheese; 25 gm. of gluten bread and butter; one baked apple. 4 P.M., a cup of coffee and milk; two raw eggs. 7 P.M., a cup of hot milk; 10 gm. of smoked beef; 100 gm. of cauliflower with butter sauce; lettuce; 100 gm. of cheese; 25 gm. of gluten bread and butter.

Rigid Diet.—For an individual weighing 60 kgm.: 8 A.M., a cup of tea with saccharin; three eggs; 50 gm. of ham. 10 A.M., a cup of bouillon with one egg. 1 P.M., a cup of clam broth; 200 gm. of fried eels; asparagus with French dressing; 100 gm. of roast lamb with mint sauce; salad; 25 gm. of cheese; a demitasse of black coffee. 7 P.M., 3 scrambled eggs; 50 gm. of broiled ham; salad; 25 gm. of cheese; a cup of tea with saccharin. 10 P.M., a dozen small clams or oysters on the shell.

Medicinal Treatment.—He had frequently found an almost specific effect from opium in diabetics who were neurasthenic. Such persons should be given at first gr. ss. of opium three times a day, one hour to one hour and a half after meals. This might be eventually increased to three times this quantity, it being a well-known fact that there was a special tolerance for opium and its alkaloids among diabetics. He also made use of Fowler's solution of arsenic and of the bromide of arsenic, the latter in doses of gr. $\frac{1}{30}$ to $\frac{1}{20}$, three times a day, given in plenty of water, after meals. The relief from mental worries and nervous shocks was the *sine qua non* in the hygienic treatment. The patient should be warmly clad, and while the skin should be kept active and in good condition by frequent bathing, cold baths and sea bathing should not be indulged in. He did not believe in the specific virtue of the waters of any of the spas, but such waters often corrected disturbances of the stomach and bowels. Phthisis was a very common complication of diabetes, and caused the death of twenty-five per cent. of the patients. In cases of diabetic gangrene the diabetic treatment must be enforced. When diabetic coma had set in, blood depletion and the intravenous infusion of saline solution should be tried, though it was far better to avert than to treat this condition.

Glycosuria and Diabetes Mellitus in Relation to Life Insurance.—Dr. E. H. Bartley, of Brooklyn, presented a portion of his paper on this subject. He said that the presence of sugar in normal urine could be detected by some of our tests which were not the most sensitive. This was now a pretty generally accepted fact. With Fehling's, Trommer's, and Nylander's bismuth test the reaction was not ordinarily obtained, though it would be observed in about one-third of the specimens of normal urine examined by the Nylander test. Under these circumstances this test yielded not a black, but a grayish color. This brought up the question of when glycosuria should be considered synonymous with diabetes mellitus. He was of the opinion that the finding of as small a quantity as could be detected by any of the three tests mentioned should call for a second examination of the urine before the acceptance or rejection of the applicant for life insurance. He had never heard until this evening of dextrose failing to reduce the ordinary test solutions. As the urine of a diabetic did not at all times show the presence of sugar, the life-insurance examiner might pass a person who was really suffering from glycosuria. It was not uncommon for such an examiner to reject an applicant because it happened at the time of the examination that, as a result of an error in diet, or from some other cause, there was present a temporary glycosuria. He knew no way of distinguishing glycosuria or true diabetes by any chemical test. Some conception of this distinction could be learned by determining the total solid matter passed in the twenty-four hours. The total solids could be approximately determined by multiplying the last two figures of the specific gravity by the number of ounces voided. The normal quantity was usually about one thousand grains. The quantitative estimation of urea was a matter of considerable importance in the diagnosis. In simple glycosuria there was not usually an excess of urea in the twenty-four hours. In life-insurance work it was ordinarily impossible to obtain the total quantity of urine for the twenty-four hours. This quantity could be approximated by having the applicant remain at the office for one hour, emptying the bladder at the beginning, and again at the end of this time. Ordinarily, about two ounces of urine would be voided, but in diabetics this quantity would often be increased to three or even six ounces. Some allowance must also be made for the time of day. The fermentation test was not altogether reliable because the administration of turpentine and other similar substances often gave rise to a condition of the urine which produced fermentation. When the quantity of sugar was very small, sulphate of copper should be added to the urine, the latter boiled, and then sodium acetate added. This removed almost all of the sub-

stances which interfered with the usual copper test. This solution was then treated with the ordinary sodium hydrate, set in a water bath and brought nearly, but not quite, to the boiling-point. This mixture should then be allowed to cool. During the cooling process the oxide of copper was deposited if sugar was present. Hardly anything else but sugar would give this reaction under these conditions.

Dr. H. D. Chapin asked Dr. Bartley what he considered to be the significance of a trace of albumin existing coincidently with sugar in the urine.

Many Locomotive Engineers Diabetic.—Dr. Andrew H. Smith called attention to the remarkable frequency of diabetes in locomotive engineers. According to the statistics of the Brotherhood of Locomotive Engineers, the proportion of diabetics in this class was five times as great as among the average of people. This, the speaker thought, was due to the very intense mental concentration incident to their work. He also thought that a lesser degree of mental attention continued for a considerable period would probably produce a similar effect, and this would account for the large number of financiers who were affected with this disease. As diabetic patients should be protected from all unnecessary worry, Dr. Smith advised that such persons should be discouraged from measuring their own urine or keeping any notes regarding its condition.

Dr. A. Rose spoke of the effect of carbonic acid gas in the treatment of diabetes, and the rationale of the method.

Dr. James K. Crook said that many hypotheses explaining the pathogenesis of this mysterious affection had been elaborated, but none of them fully met the objections or satisfied the demands of the present generation of investigators. He had himself been strongly impressed with the probability of the nervous origin of the disease. It appeared to be established that in every case of essential diabetes there was more or less hyperæmia of the liver, due to a paralysis of the vasomotor nerves of the organ. It was well known in the treatment of the disease that agencies producing a dilatation of the superficial blood-vessels, thus relieving hepatic congestion, effected a diminution in the amount of sugar in the urine and a temporary improvement in the symptoms. Many years ago Claude Bernard had demonstrated the fact that irritation of the floor of the fourth ventricle, corresponding to the roots of the pneumogastric nerve, would produce hyperæmia of the liver, followed by transient glycosuria. Subsequent observers had shown that mechanical excitation of other portions of the vagus and sympathetic nerves was followed by the same results. Still later it had been learned that various influences operating upon any portion of the sympathetic tract, or involving the peripheral distribution of the vagus, would produce temporary glycosuria. Among these might be mentioned embarrassments of respiration, due to asthma, to strangulation, to the use of anæsthetics, and the action of certain irritant poisons, like woorara, strychnine, and phosphoric acid. Certain psychic influences—grief, shock, anxiety, etc.—produced the same results through the medium of the vagus and sympathetic nerves. The speaker thought the long-continued operation of nervous strain was responsible for the frequency of diabetes among locomotive engineers, as had been demonstrated by Dr. Smith. It had further been observed that traumatisms of the brain and spinal cord were often attended by glycosuria. A considerable proportion of these neurogenic cases passed into true diabetes. The relation of the pancreas had not been fully worked out, but it had been the speaker's opinion that the intimate connection of this organ with the sympathetic system was responsible for whatever influence it possessed in the pathogeny of diabetes. However, as opposed to the theory of the nervous origin of this disease, there existed several important pathological and clinical facts. Autopsies in diabetic cases had failed to show the pathological alterations which ought to be present in some portion of the nerve centres or supplying cords. Again, serious organic diseases of the brain and spinal cord were not frequently attended by true diabetes; nor, if we except Basedow's disease, were functional nervous troubles associated with the affection with notable frequency. Furthermore, it had been observed that many of the diseases of the liver itself, even those producing the greatest amount of hyperæmia, were quite free from the manifestations of diabetes. Notwithstanding these apparently contradictory facts, however, the speaker thought that the positive implication of the nervous system in many cases of true diabetes, plus the not infrequent involvement of the pancreas, constituted the most important factors upon which to found a satisfactory explanation of its pathogenesis.

Dr. Stern said that he had studied very carefully the mortality statistics of New York City and had found out of one hundred and two males dying of diabetes that sixty-six had been in the tenement houses. He had seen many cases of diabetes in which the urine had not responded to the usual tests for sugar in the urine.

Dr. Stark said that fully one-third of the cases presented albumin in addition to sugar in the urine, but it was of no special significance unless accompanied by other indications of nephritis.

Dr. Mayer said that he did not find albumin in such a large proportion of cases, and looked upon it as of considerable significance, because it indicated the destruction of the epithelial covering of the Malpighian tuft.

Dr. Bartley, in closing the discussion, said that he had always looked upon the occurrence of albumin as an indication of serious mischief. Both the copper and the bismuth tests were fairly reliable if employed in urine which had been subjected to the preliminary treatment. He had insisted that dextrose could not be present in the urine without responding to the tests for this substance; he had not intended to say that he had never seen diabetes in which the urine had failed to respond to the tests for dextrose.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 30, 1901:

	Cases.	Deaths.
Tuberculosis	286	195
Typhoid fever	25	11
Scarlet fever	709	38
Measles	313	8
Diphtheria and croup	268	47
Smallpox	41	10
Varicella	75	0

Tobacco Alkaloids.—According to Dr. Thoms there are two alkaloids present in cigars, nicotine and pyridine, the latter being derived from the former. The stump contains four times as much nicotine as the smoke, and as the average cigar contains only 1.12 per cent. of nicotine, comparatively little of either alkaloid ever reaches the mouth. The only constituents that could be harmful are carbon monoxide, produced to the extent of 20 c.c. for each kilogram of tobacco, and an ethereal oil. The former can probably be ruled

out. The latter, consisting of pyridine, a phenol, and probably furfurol, but very difficult of analysis, is highly poisonous, causing the symptoms commonly associated with tobacco poisoning.—*London Globe.*

Health Reports.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 30, 1901:

		Cases.	Deaths.
Smallpox—United States and Insular.			
California, Los Angeles	March 19th	15	
San Francisco	March 2d to 9th	8	
District of Columbia, Washington	March 18th	16	
Florida, Jacksonville	March 16th to 23d	2	
Illinois, Anna	December — to March 18th	50	
Chicago	March 16th to 23d	10	
Kansas, Wichita	March 16th to 23d	12	
Kentucky, Lexington	March 16th to 23d	2	
Louisiana, New Orleans	March 16th to 23d	14	2
Michigan, Bay City	March 16th to 23d	2	
Detroit	March 16th to 23d	6	
Minneapolis	March 16th to 23d	6	
Winona	March 16th to 23d	10	
Nebraska, Omaha	March 9th to 23d	12	
N. Hampshire, Manchester	March 16th to 23d	3	
New Jersey, Hudson Co	March 21st	6	
Newark	March 16th to 23d	1	
New York, New York	March 16th to 23d	41	6
Ohio, Cincinnati	March 15th to 22d	2	
Cleveland	March 16th to 23d	43	1
Toledo	March 16th to 23d	1	
Pennsylvania, Pittsburg	March 16th to 23d	9	
Steelton	March 16th to 23d	6	
South Carolina, Greenville	March 8th to 16th	2	
Tennessee, Memphis	March 16th to 23d	26	
Nashville	March 16th to 23d	13	
Utah, Salt Lake City	March 16th to 23d	40	
West Virginia, Huntington	March 8th to 16th	12	
Wheeling	March 8th to 23d	2	
Wisconsin, Milwaukee	March 16th to 23d	2	
Porto Rico, Ponce	March 11th	13	
Smallpox—Foreign.			
Austria, Prague	February 23d to March 9th	10	
Trieste	March 2d to 9th	2	
Brazil, Rio de Janeiro	January 1st to 31st	36	
Belgium, Antwerp	February 23d to March 9th	8	
Ceylon, Colombo	February 8th to 16th	1	1
Ecuador, Guayaquil	February 2d to March 2d	..	14
Egypt, Cairo	February 25th	..	1
France, Paris	March 2d to 9th	..	7
Roubaix	January 1st to 31st	..	1
Germany, Leipsic	February 16th to 23d	..	1
Great Britain, England, London	March 2d to 9th	1	
Newcastle-on-Tyne	March 2d to 9th	2	
Scotland, Edinburgh	February 2d to 9th	3

* In German colony.
† Thirty-five or forty per cent.

Cost of Hospitals.—The enormous cost of erecting buildings for the care of the afflicted is illustrated in the case of the proposed lunatic asylum for Edinburgh. The estimates amount to about £380 ($1,900) per bed or upward of £380,000 ($1,900,000) for the thousand beds. This is exclusive of a site costing about £21,000 ($105,000), of a railway for the conveyance of materials for building, etc., at a cost of £33,000 ($165,000), and of a water supply estimated at £16,000 ($80,000)—*The London Hospital.*

Lady Medical Residents.—It always appeared, remarks the *Medical Press*, to be an anomaly that in the Royal Free Hospital, which is reserved to female medical students, the resident appointments should have been monopolized by men. The reasons for this favoritism have never been clearly stated, possibly because, like the snakes in Ireland, "there aren't any." Be this as it may, it has been decided that in future appointments are to be allocated to qualified women who are entitled to the advantages which these posts offer in the direction of gaining practical experience. The only difficulty which is anticipated is that sisters and nurses may object to taking orders from "uppish" young ladies; but we have known this to happen toward "uppish" young men. With a little tact no friction should occur, and the Royal Free Hospital, peopled by female students and officered by medical women, should be in a fair way to become a medical Lesbos.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

REMARKS ON ENTEROPTOSIS.[1]

BY MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

ENTEROPTOSIS, or Glénard's[2] disease as it has been justly called, has been known since 1885. Although fifteen years have passed since the subject was first broached by Glénard, there still exist many controversies and unsettled questions in regard to it. A discussion on this topic appears the more appropriate, as it is of great practical bearing. Before treating this subject and stating my views, it will be essential to give an exact definition of the term enteroptosis. Enteroptosis (ἔντερον intestine, πτῶσις descent) means a falling down of the intestine. Glénard applied this term, however, to signify not only a ptosis of the bowel, but also conditions in which several organs of the abdominal cavity have left their normal places and sunk lower down. Thus, according to Glénard, enteroptosis characterizes generally a prolapse of one or (usually) more abdominal viscera. A descent of each organ separately is called by its own name, with the addition of the suffix "ptosis," thus gastroptosis, nephroptosis, coloptosis, hepatoptosis, splenoptosis, metroptosis, etc.

Ewald[3] used the term enteroptosis in the same sense as Glénard. Stiller[4] applies the word enteroptosis in a much wider sense, for he says: "Enteroptosis and nervous dyspepsia are identical; atony is its most constant, often its only symptom."

Kuttner and Dyer,[5] Rose,[6] Lockwood,[7] and McPhedran[8] employ the term gastroptosis to signify a prolapse of the stomach, combined with that of other intestinal organs. Although gastroptosis is a very significant sign of enteroptosis—for accompanying the descent of the stomach there must also necessarily be a ptosis of the colon—I am not of the opinion that we should use this term for Glénard's disease. The expression gastroptosis lays too much weight upon the stomach, which may lead to a wrong impression of the disease and its treatment. I am in favor of the word enteroptosis as originally outlined by Glénard. This will then include a descent of several organs of the abdominal cavity (stomach and colon, one or both kidneys, and occasionally the liver, spleen, etc.). It thus signifies a general tendency for the abdominal organs to prolapse. While, however, I am perfectly in accord with Glénard in regard to the use of the term enteroptosis in its anatomical sense, I think that, clinically, this well-known writer ascribes too many ailments to this condition. In my paper on enteroptosis[1] I have already referred to the facts that enteroptosis may exist without giving rise to any symptoms whatever, and again that enteroptosis may be accompanied by all kinds of gastric and intestinal affections. This view has been corroborated by Kuttner and Dyer, and lately also by Lockwood.

Etiology.—In my papers on enteroptosis, movable kidney,[2] and floating liver,[3] I have already discussed this subject of etiology of prolapse of the abdominal organs. The corset seems to be an important factor in the causation of these anomalies. In addition to what I have already published about this modern piece of wearing-apparel, I would like to mention the following writers as bearing testimony to the ill effects of the corset:

Dickinson[4] has made an extensive study of the influence of the corset upon the chest and abdomen, and I take pleasure in citing a few of his conclusions: "The estimated total pressure of the corset varies between thirty and eighty pounds. The capacity for expansion of the chest was found to be restricted one-fifth when the corset was on. The thoracic character of the breathing in women is largely due to corset wearing. The abdominal wall is thinned and weakened by the pressure of stays. The liver suffers more direct pressure, and is more frequently displaced than any other organ. The pelvic floor is bulged downward by tight lacing, one-third of an inch."

Kellogg[5] is also a firm believer in the injurious effect of the corset. He expresses himself in the following manner: "Certainly no other reason can be given for the abnormal waist of the civilized woman than the fact that this portion of the body has been subjected to abnormal pressure in such a manner as to prevent natural development, and to compel the acquirement of a deformity." According to his views, first, downward displacement of the abdominal and pelvic organs takes place; secondly, the muscles of the trunk do not develop. In one hundred and fifty cases of pelvic disease, the stomach and bowels were displaced in one hundred and thirty-eight cases. "The so-called abdominal respiration is unnatural and unhealthful—indeed, it has been in many cases productive of serious injury." Kellogg is against all sorts of corsets. "The only correct principle is to suspend everything from the shoulders by means of a

waist which will equally distribute the weight upon natural bearings, and at the same time give latitude for the greatest freedom of waist movement."

Bouveret[1] says briefly: "A corset is the most frequent and the most effective cause of enteroptosis."

Wolkow and Delitzin,[2] in their extensive experimental studies in regard to the etiology of movable kidney, make the following statement in reference to the influence of both corsets and belts upon the development of this condition: "1. The use of the belt may dislocate the kidney downward, may fix it, and even move it upward, according to the direction of pressure exerted by the belt. The use of a high belt is of greatest harm. A belt in the plane just below the twelfth rib fixes and even supports the kidney, and in this respect seems to exert a favorable influence. 2. The corset fixes the kidney as long as it is laced, but may increase the mobility of the kidneys by altering the form of the perivertebral spaces in a manner unfavorable for the fixation of the kidneys. It thus acts as a recurrent trauma, and must generally be counted among the unfavorable factors in relation to the so-called mobility of the kidneys. 3. The most plausible explanation of the influence of the belt and corset is found in their action upon the shape of the perivertebral spaces."

The corset is certainly not the only cause. Enteroptosis is occasionally found in very young women who have never worn a corset, and also in men. A constitutional weakness has been assumed by several writers. Thus Tuffier says: "Nephroptosis is one of the symptoms of a probably congenital weakness of the tissues." The theory of a congenital weakness of the tissues has found considerable support in the teachings of Stiller. This able clinician discovered that almost all of the patients with enteroptosis presented a floating tenth rib. Normally, as is well known, only the eleventh and twelfth ribs are floating, while the tenth is attached by means of cartilage to the thorax. This or the costal stigma of Stiller, although an important sign, cannot be considered an absolute proof of enteroptosis. While it is found with but very few exceptions in Glénard's disease, it can also quite frequently be discovered in other conditions which have nothing in common with enteroptosis. It is, however, of value as indicating that in enteroptosis very frequently some congenital anomalies are encountered.

Schwerdt[3] considers enteroptosis a constitutional disease. Concerning the etiology, the corset, according to him, plays an important rôle, by encouraging inactivity of several thoracic muscles. "This is the first harm the corset does. Secondly, it restrains the mechanical and chemical functions of the digestive and respiratory apparatus, and thus lessens nutrition. Thirdly, it causes diseases of the blood, by encroaching upon its unlimited mobility, its first and most essential biological property. In the fourth place, it contributes largely to the maintenance of equilibrium, but at the same time injures important functions of our nervous system, viz., the sense of equilibrium and the muscular sense, which, like everything organic, can be kept in perfect condition only by constant use."

A weakened condition of the abdominal walls appears to be a primary and most important factor in the causation of enteroptosis. This relaxation of the abdominal parietes leads to a diminished tension within the cavity, and thus also to disturbances of equilibrium of the abdomen. In regard to this point, Wolkow and Delitzin express themselves in the following manner: "The muscular layer of the anterior abdominal wall is not only of physiological, but also of anatomical significance for the fixation of the abdominal viscera. Take away the influence of the abdominal layer and the equilibrium of the abdominal organs will be disturbed. In very many cases the intestinal convolutions assume a deeper position, and, in consequence of the hermetic condition of the abdominal cavity, a retraction of the meso- and epigastrium takes place. The kidneys descend, rotating with their lower poles to the front, the right usually in a higher degree than the left. In this condition kidneys that could not be felt become accessible to palpation, those that could be palpated before sink deeper and are more plainly to be felt. Kidneys that could be reached only while the patient was standing can now also frequently be felt in the reclining position. The cause of the greater accessibility of the kidneys is to be sought partly in the thinness of their abdominal covering, partly in a dislocation of the intestinal convolutions away from the kidneys. In all these relations there are essential individual differences, so that in some cases, in spite of a marked thinness of the abdominal wall, the kidneys cannot be reached, probably in consequence of other conditions which increase the mobility or the difficulty of palpation of this organ."

The same writers again make the following remarks: "Nephroptosis is only a prominent symptom of a certain pathological condition, a symptom that is most apparent and which alone causes great functional disturbance. This symptom is an infallible index of an existing alteration of the intra-abdominal equilibrium, and, looked at from this standpoint, the study of so-called mobility of the kidney assumes special importance."

Monteuuis[1] likewise lays much stress upon a weakened state of the abdominal walls.

He says: "Owing to a lack of tone and resistance in the abdominal muscles, the relations of the viscera to each other are not preserved. In consequence of occasional causes—such as coughing, vomiting, which frequently escape notice in looking for the etiology of the condition, on account of their being so much out of proportion with the affection which they produce—grave changes in the abdominal equilibrium take place. This tendency of the abdominal wall may be natural: it certainly is developed by the use of the corset. Its exaggerated constriction results, in fact, in the emaciation, atrophy, and subsequent relaxation of the abdominal wall."

Although in many instances the weakness of the abdominal walls takes its origin in a congenital disposition to this anomaly, there is no doubt that cases are met with in which a congenital factor certainly does not come into play. To the latter category belong those instances of enteroptosis which develop after rather sudden great losses of flesh, no matter what their cause, and also after abrupt changes in the volume of the abdominal cavity.

Frequency.—In as far as enteroptosis is accompanied, in most instances, by a movable kidney, the latter can also be taken as an index for the occurrence of the former. It is quite interesting to note that the occurrence of either enteroptosis or movable kidney can be gauged only by clinicians who are well versed in the examination of these anomalies. In 1882 the well-known surgeon Lawson Tait[2] denied the existence of a movable kidney. I cite his own words: "I have had a large number of cases sent to me as instances of floating kidney, but they have all turned out to be distended gall bladders and ovarian tumors

with exceptionally long pedicles. My scepticism is, therefore, excusable."

The frequency of enteroptosis has been stated by Glénard as being about one to four in female patients suffering from digestive disorders. With regard to nephroptosis, Glénard, whose big statistics include all the cases he saw up to 1893, encountered among 3,788 patients 481 cases of nephroptosis, or 12.7 per cent. Of these there were 2.7 per cent. in men and 22 per cent. in women.

Wolkow and Delitzin found among 221 women 66 cases of movable kidney (30 per cent.). While most writers agree that enteroptosis, as well as movable kidney, as such, are principally found in women, and only a small percentage is found in men, McPhedran[1] and Stiller have a different view on this subject. McPhedran says: "The causation of gastric and other visceral prolapses is a complex one. It is said to occur with much more frequency in women than in men. With this my observations are not in accord. Of the last 45 cases carefully examined, 26 were in females and 19 in males. In 6 of the males and 12 of the females the ptosis was marked." Stiller, discussing the same subject, remarks: "My own experience shows that the number of cases in males is only ten to fifteen per cent. less than in females." The reason for this discrepancy of the latter writer's view with that generally accepted, lies in the different conception of the word enteroptosis. As already mentioned above, Stiller calls every case of functional and nervous disorder of the digestive apparatus enteroptosis.

In my previous papers I have been able to corroborate Glénard's statement with regard to the frequency of enteroptosis, and also with regard to its much greater prevalence among women. Thus, among the patients with digestive troubles examined during the month of January, 1896, there were found 6.2 per cent. of enteroptosis in males and 34.8 per cent. in females.[2] The frequency of movable kidney amounted, as stated by me in another paper,[3] to 1.81 per cent. in male, and 20.6 per cent. in female patients with digestive disorders. Inasmuch as statistical material gains in value the greater the number from which the deductions are made, I took the trouble to examine all my private patients of this year (January 1 to December 1, 1900) with regard to the occurrence of visceral ptoses. The greater contingent of my cases consisted of patients with digestive disorders. The total number amounted to 1,912 patients—1,080 males, 832 females. Among these there were encountered 347 cases with ptoses of the abdominal viscera, 70 among the men and 277 among the women. Among these there were 240 cases of enteroptosis, 20 in men and 220 in women.

Most of the cases of enteroptosis were accompanied by a movable kidney, namely, 212; 18 in men and 194 in women. The saying of Trastour: "Movable kidney is the habitual satellite of enteroptosis" appears thus to be correct. Among the cases of enteroptosis with movable kidney, 23 had also a descent of the liver, 3 men and 20 women. Enteroptosis with floating liver, unaccompanied by movable kidney, was noted in 12 cases, 1 in a man and 11 in women. Enteroptosis alone (the kidneys and liver being in their places, the only symptoms being a descent of the stomach and a strong pulsation of the abdominal aorta) was found in 15 cases, 1 male and 14 female. Movable kidney alone, not accompanied by general enteroptosis, was encountered 57 times, 21 in males and 36 in females. Floating liver alone was found in 39 cases, 25 male and 14 female.

7.—Hepatoptosis and Gastroptosis.	1	—	1	0.05	—	0.12
8. Splenoptosis.	1	—	1	0.05	—	0.12

The first table shows the different varieties of splanchnoptosis and their relative frequency in men and in women. The second table gives the relative numbers of movable kidney in the two sexes and also the degree of mobility, as well as the relation of frequency of movable kidney on the right or left or both sides.

Symptomatology.—It is well known that enteroptosis may exist without giving rise to any symptoms whatever. In most instances, however, various morbid manifestations are encountered. The latter are not always due to enteroptosis alone, but rather to coexisting disorders of the digestive tract. In the following lines I shall try to describe the symptoms, which must be assigned to the enteroptosis alone. The patient often complains of a faint feeling or a certain weakness after rising. There is frequently a feeling of considerable fatigue after slight exertion, principally after walking. In women the sensation of fatigue is also combined with pronounced backache. A feeling of weight is occasionally experienced in the lower half of the abdominal cavity, while a dragging sensation is felt in the epigastric region. Flatulence is often encountered, constipation is present in most of the cases, and frequent micturition in a considerable number. Aside from these direct symptoms, it is safe to say that any disease of the digestive tract, complicating

[2] Max Einhorn: "Enteroptosis." Med. News, September 19, 1896.

[3] Max Einhorn: "Movable Kidney and its Treatment." MEDICAL RECORD, August 13, 1898.

enteroptosis, does not show the same tendency to yield to the usual remedies as normally. The abnormal position of the abdominal viscera produces a weakening effect upon the resisting-power of the organism and its energy in combating maladies, especially when the latter exist in them. This explains why the greater part of patients with enteroptosis are troubled with one or the other variety of stomach or bowel disorder, or both. Cases of enteroptosis, lasting a long period, frequently lead to pronounced anæmia, in consequence of subnutrition. The latter gives rise to a host of nervous manifestations (neurasthenia).

As a good instance of the subjective symptoms of enteroptosis, I beg to describe the following case:

December 2, 1900.—Moses C——, thirty years old, has been suffering for a long time from constipation. He has had this since childhood, as far back as he can remember. He has never vomited, but suffers from distress in the stomach. This organ feels as though suspended and filled with a heavy weight. Often it feels as if it were bobbing up and down, quivering once or twice. He declares that he is conscious of having a stomach. He can eat everything, but sometimes even a glass of water will produce a feeling of distress. He sleeps well, but has no appetite, and is troubled a good deal with flatulence. On rising he feels bad, having sometimes nausea.

Present condition: A very nervous, slim young man. The heart and lungs are normal. The stomach reaches two fingers below the navel; the liver is somewhat descended, about one finger below the right costal margin. The right kidney, on deep inspiration, can be palpated in its lower third. Chemical examination of stomach contents one hour after the test breakfast shows the presence of free HCl and a total acidity of 80. Weight, one hundred and thirteen pounds.

Objective Symptoms.—Patients with enteroptosis are, as a rule, thin and slender, and often appear younger than they really are. The abdominal walls are generally flaccid, and the abdominal cavity appears to be too commodious for its contents. Palpation is extremely easily executed in these patients, there being, as a rule, no rigidity of the muscles. When the patient stands, the lower part of the abdomen shows a round protrusion, which begins at the navel, while the epigastric region presents a caved-in appearance. This is principally found in female patients. In the latter, a pendulous abdomen may be encountered, especially in patients who have had children. In the same class of patients diastases of the recti muscles are occasionally met with.

The stomach occupies a low position—gastroptosis—that means the greater as well as the lesser curvature has been pushed downward. The abnormal position of the stomach can be easily demonstrated by the following three procedures:

1. Splashing sound. 2. Inflation of the stomach with gas. 3. Gastrodiaphany. The most convenient and easiest means is the splashing sound. On tapping, principally upon the left side of the abdomen below the margin of the ribs, in a partly filled condition of the stomach, there will be no sound audible immediately below the ribs, while somewhat farther down in the region of the navel, above and below it, the splashing can be distinctly heard. The area over which this splash can be produced will indicate the position of the stomach. Inflation of the stomach with gas, as well as gastrodiaphany, will certainly distinctly show the descent of the stomach; but these procedures, being a little more complicated, will be reserved for doubtful cases.

Strong pulsation of the abdominal aorta is frequently encountered, and is probably due to the partial uncovering of this vessel by the slipping down of the stomach. The transverse colon, the cæcum, and part of the ascending colon, as well as the sigmoid flexure, can often be distinctly palpated. The transverse colon is frequently found in these cases as a ribbon-like body running horizontally above the navel. This Glénard designated as "corde colique transverse," and

concluded from the size of the cord, which is considerably smaller than we should expect the colon to be, that there is a condition of enterostenosis, or a narrowing of the bowel. Ewald and others are of the opinion that the ribbon-like body felt, does not represent the colon, but the pancreas. My own view, however, coincides with that of Glénard. For in some instances the *corde colique* is found in the region of the navel, or even somewhat below it—where the pancreas never exists—and again occasionally in palpating this transverse band a gurgling sound is heard. Furthermore, it can sometimes be traced to the ascending colon.

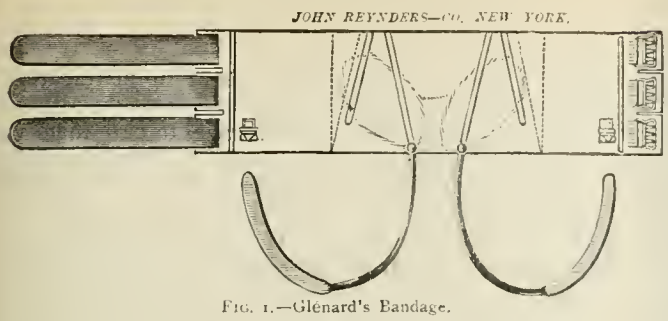

Fig. 1.—Glénard's Bandage.

The right kidney is often found movable, occasionally both kidneys are, seldom the left kidney and the spleen. The liver may also partly or wholly descend, and thus a more or less considerable surface of this organ will be accessible to palpation. In females a prolapse of the uterus is not infrequently found. Apparent tumors of the abdomen[1] are occasionally encountered in patients with enteroptosis. The method of examination for movable kidneys and floating liver is well known, and can also be found described in my previous papers.

Diagnosis.—The diagnosis of enteroptosis is quite easy. It is only necessary to think of this condition, and it is not likely to escape detection. The subjective symptoms above detailed, in conjunction with the result of a thorough examination of the abdomen by the usual physical methods, will reveal the presence of enteroptosis. Another auxiliary in diagnosis of this condition is the so-called Glénard's "belt test." The physician, standing behind the patient, encircles the lower part of the abdomen of the latter with both his hands, at the same time supporting and partly lifting it. The patient is now asked if this procedure gives him relief. If so, it speaks in favor of the presence of enteroptosis.

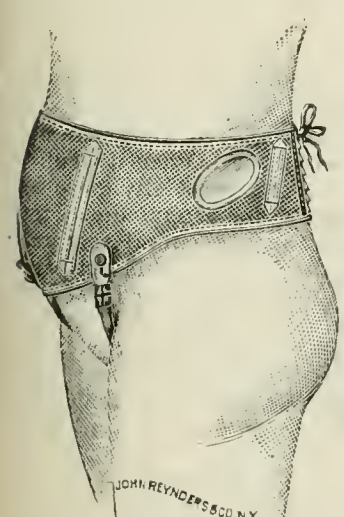

Fig. 2.—Bandage with Holes over the Iliac Crests, and Straps around the Legs, as generally used by the writer.

Prognosis.—The prognosis of enteroptosis is good. When appropriate treatment is instituted, an amelioration in the condition of the patient quickly takes place. Whether a full *restitutio ad integrum* can take place is not yet definitely settled. With regard to this point it is interesting to note that, as early as 1883, Henderson[2] reported a perfect cure in a patient with movable kidney, within the short period of two and a half months. His remarks are very appropriate even now: "Nowadays, when the surgeon boldly invades the great cavities of the body—clearing out tubercular vomicæ, freeing an impacted gall duct, stitching a displaced kidney to the lumbar muscles, and in other ways threatening the position of the physician in his own domain—it behooves the latter, in friendly rivalry, as well as for the general good, to show that his art does not end with the diagnosis of abnormal conditions, but also extends to their successful removal." From my own experience I would say that a perfect cure of enteroptosis is possible. I know of positive cures—that is to say, the stomach has returned to its normal position, and a movable kidney has disappeared—in more than a dozen cases of my own. As a good instance of such a cure, I will describe the following case, which was very recently under my observation:

Miss Mary G——, twenty-six years old, was troubled with her digestive organs as far back as she could remember. She had always suffered from severe constipation. Her appetite was poor; she frequently had slight pains some time after meals. She often felt somewhat faint some time after rising, and was hardly able to walk any considerable distance, on account of the great fatigue and backaches which overcame her. On examination I found that the chest organs were intact. The stomach extended four fingers' widths below the navel, while the lesser curvature could be found two fingers above the navel. Both kidneys were movable, the right in the fourth and the left in the second degree. After being treated for about two months with ample feeding, intragastric faradization, and an abdominal bandage, she steadily improved. I will also add that during this time she took a great deal of out-door exercise (bicycling, rowing, walking, golfing, etc.). In this short period she gained fifteen pounds in weight, felt well in every respect, was strong, could eat everything, and her bowels moved quite regularly. A new examination of the abdomen showed that the stomach now extended only down to one finger above the navel, while neither of the kidneys could be palpated.

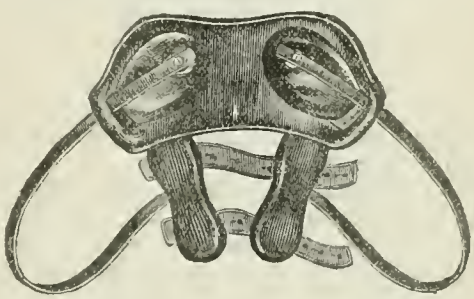

Fig. 3.—Hard Rubber Abdominal Supporter.

Treatment.—The principal part in the treatment of these cases consists in the application of a well-fitting abdominal supporter, ample nutrition, and exercise. The bandage should support and partly lift the lower part of the abdomen. The accompanying illustrations show various abdominal supporters commonly used. It is immaterial what kind of a bandage is used if it only fulfils the above purpose. The bandage should be provided with windows over the iliac crests, also with straps at the thighs, which prevent its slipping up. Special pads for a movable kidney or a floating liver are, according to my opinion,

Fig. 4.

[2] F. Henderson: "A Case of Movable Kidney Permanently Cured." The Glasgow Medical Journal, vol. xx., 1883, p. 329.

of no value. A. Rose recommended the use of adhesive plaster over the lower part of the abdomen, instead of the bandage. In some instances this procedure may be tried.

Ample nutrition is certainly important, perhaps more so than the bandage. This must be effected by all means. The diet may, in instances in which the condition of the gastric secretion is known, be adapted more or less to it. But this is not so essential as the knowledge that we should make our patients eat more than is absolutely necessary for the maintenance of the balance of the body. As a rule, frequent meals, plenty of bread and butter, good, plain food, with no very indigestible substances, are indicated. I usually have the patients take milk, and bread and butter between meals. In this regard I differ somewhat from Glénard,

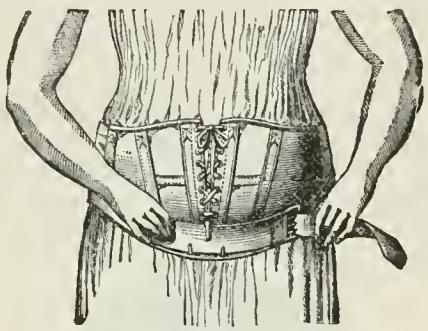

Fig. 5.—Teufel's Abdominal Supporter.

who is of the opinion that milk is especially harmful in this class of patients.

Exercise is another important factor in strengthening the constitution generally, and the abdominal muscles particularly. Out-door sports seem to be especially adapted for this purpose. Massage has also been warmly recommended. According to my opinion, however, this is of value only in cases with mild enteroptosis, but not in greatly anæmic patients, or in the advanced cases, for it often creates too much irritation, and may even give rise to inflammatory processes in the abdominal cavity, especially if vigorously executed.

Electricity seems to be especially adapted, when administered intragastrically, to cases in which there are manifold functional disturbances of the stomach.

Of medicaments, iron and arsenic are often indicated in anæmic conditions, while the bromides may be given to allay great nervousness. All the digestive disturbances should be managed according to the general rules. This applies also to the constipation which is so frequently found in enteroptosis. Too many laxatives, however, should not be given, nor is there any need of a laxative treatment in cases in which regular movements are present.

Anatomical Researches in Regard to the Cæcum and its Appendix.—Giuliano Perondi, from studies upon cadavers, found among other things that the most frequent seat of the cæcum was the inferior iliac region, and that it was nearly always completely invested by peritoneum. The form of the appendix was usually cylindrical, sometimes cylindrico-conical, and occasionally rosary-like. Out of fifty cases, it was subperitoneal in five, intraperitoneal in forty-two, partly sub- and partly intraperitoneal in two. The average length was 7.6 cm. (in one case 16.5 cm.), average breadth 0.5. The ileo-appendicular fold was usually inserted inferiorly on the appendix or near it. No folds or fossæ were found in any case behind the cæcum, but always behind the beginning of the ascending colon.—*Il Policlinico*, February, 1901.

SMALL HOSPITALS AND THEIR ADMINISTRATION.[1]

By LOUIS N. LANEHART, M.D.,

HEMPSTEAD (L. I.), N. Y.

There remains very little to be said in justification of the hospitals of large cities. No longer is their death rate so large that there is need to call them in solemn irony "houses of recovery," to controvert the natural repulsion of the general public. The black night of ignorance when hospital beds were built for economy's sake to contain four patients, but often held six—with smallpox, surgical and general illness, indiscriminately jumbled together—has vanished before the double light of bacteriology and humanity; and hospitals are now recognized as giving honest service as well to the patients as to the education of the profession. The association of the medical men of the highest standing with the large hospitals, as well as the low death rate, the large number of patients returning to sing its praises to their neighbors, all assure the city hospitals a place in the respect and affection of the community.

Not so, however, with the rural hospitals. They are frequently looked upon askance by the members of the medical profession not in immediate association with them, and are not altogether free from the suspicion of grave inefficiency by the laity as well. There are of course a number of these hospitals that are far from being ideal institutions, yet I know of no instance in which the physicians and the community have not been made better by the presence of even these. But there assuredly are those whose work is of the highest character—quite equal to the average large city hospitals; yet because of their location in the country they do not receive the appreciation due them.

The small country hospital usually has its origin in the ambition of medical men wishing to have at command means for the proper study of their cases, and who are also dissatisfied with the wholly inadequate methods pursued in the care of the sick poor. A few physicians in the community who are possessed of this ambition for better work will unite with the more progressive of their friends and patients to form a hospital association.

It is difficult to conceive of any community of moderate population where modern medical methods are dominant, in which a hospital is not needed. All medical men know that most cases of illness are best taken care of in a hospital, but it is often difficult to make the people understand this, especially those living in the country; there is the natural dread that ignorance has of institutions, the natural fear that helplessness feels among strangers. This antipathy is less, however, toward a hospital in their immediate neighborhood than toward the city hospital. The nervous strain of the great city is exhausting to a weak patient, especially to one unused to its rush and roar. Not only is the absence of fear in favor of the home hospital, but to journey a long distance is in itself often fatal.

While the proportion of homeless sick is not so great in the country as in the city, yet there is a sufficient number of them to merit consideration, and the number of homes unsuitable for the care of the sick is very large. The burden of the farmer's wife is usually heavy enough to make the care of severe illness a breaking-strain.

The nearest hospital is none too near to convey cases of painful accident and patients requiring immediate operation. With an efficient staff, including special consultants who are willing to serve in rare and obscure cases, the small hospital should receive

[1] Read before the Medical Society of the State of New York.

not only all the hospital patients of its community, but the hearty support of its physicians and of the benevolently disposed.

Granted, then, that the small hospital is, in spite of the polite incredulity of the city man, both desirable and necessary, the question of its organization arises. In establishing a hospital, no matter how small, it should be regularly incorporated, in order that it may receive gifts and bequests and hold property; and in this State it must receive the approval of the State board of charities.

The number of trustees or members of the board of managers should be sufficiently large to insure a wide-spread interest; thirty is a convenient number. They should be chosen from the members of the association. At the first election after the board is chosen three groups of ten each should draw by lot slips indicating terms of one, two, and three years' service. At the following elections, ten should be chosen to succeed the retiring group for a term of three years; this insures a certain permanence in the character of the board. All persons become members of the association on the payment of a certain sum yearly, or life members on the payment of a much larger amount.

As women are the leisure class in this country, they often have both natural inclination and time to do efficient work on hospital boards; the majority of the board of trustees, therefore, will probably be well-to-do and experienced women of the surrounding country-side. It is also essential, however, that there should be some active business men on the board, and that hospital is a wise one that gives a goodly representation to physicians on the board of management. It seems to be a general impression among those who have had considerable experience with hospital work that more hospitals have failed through the overzealous administration of women managers than from any other cause; if this be so, it has been due to the men's shirking work, and giving women responsibilities for which they have had no training in their past experience. *A priori* reasoning undoes the most brilliant woman's mind. Certainly, with a little common sense the immense power and influence of women will be directed in the channel where they will be of invaluable good to the hospitals.

The president of the board need be neither the most prominent nor the wealthiest member of the community. If either of these, his influence is apt to be greater than his knowledge of hospital matters warrants. Just a tactful man of good reputation and intelligence, who is not easily offended or agitated, is what is most desired. He should, however, have time to devote to administration, and any department tending to slackness should feel his stimulating hand.

Women make the best members of the house, wardrobe, visiting, and training-school committees. The chairman of each committee should have a place on the executive committee; the president, vice-president, treasurer, secretary of the association, and chairman of the medical staff should be the other members; and if, as is generally the case, these last-named are men, the result is usually an exceedingly well-balanced committee. The success of a rural hospital depends largely on the matron; as no resident physician is at first practicable, the matron will have double responsibility. She should be of good education and manners, of unquestionable character, and of executive ability and decision; a graduate preferably of a training-school that has a wide reputation for excellence. She should be absolute in authority within the hospital, under the direction of the executive committee only. Should the members of the various committees have ground for complaint or criticism, they should, through their chairman, report the matter to the executive committee for action. It is just here that the undisciplined woman of social habits may seriously injure an institution which really has her good will. Not sure enough of herself and her ground of complaint to risk bringing her criticism to the executive committee, she will yet foregather with friends, even more inadequately informed, and go over her surmises and inferences till thousand-tongued rumor spreads damaging reports throughout the countryside. It should be continually impressed upon the members of the various committees that any matter serious enough to warrant public criticism should first, for the good of the institution with which they are connected, be reported to the executive committee for investigation.

Under the matron must be an adequate corps of nurses. Here the rural hospital will encounter difficulties. Trained nurses who are successful are scarcely to be had by the resources of a small hospital, and the distracted management, after an enlightening experience with those available, will usually hail the suggestion of training their own nurses. The comparatively new profession of trained nurse appeals to many women to whom self-support is necessary or desirable, and to others financially independent it often offers as an avocation. With an efficient matron there should be no great difficulty in obtaining for training young women from twenty to twenty-seven years of age, of a credited character, of good physical condition, and of sufficient, say high-school, education. Good service will be secured in this way, for the nurses will realize that their future depends upon the work of each day, and the course of three years assures the identification of a nurse with her hospital and certifies her loyal service.

The medical staff would at first sight present some difficulties in the formation of a rural hospital. It must be large, as all the patients the hospital may hope to receive until its reputation is established will come from the staff's collective practice. The staff should be composed of progressive men from every section of the constituency; the men whose work and character are a guarantee of the high standard of the hospital, men who will use the opportunities of a hospital rightly; men who love their science for its own sake. The purely commercial medical man should have no place on the staff. Among the number selected for the staff there will generally be so great a diversity of tendency and interest as to meet all the requirements of good work. Two or three thoroughly trained surgeons are necessary at the beginning; a bacteriologist, a pathologist, and a neurologist are necessary, and can generally be found or developed. If added to these are men who can do, or can be taught to do, creditable eye and ear, throat and nose work, the hospital may be considered to be on a firm foundation. To the physicians forming the staff the hospital is of incalculable benefit, although they sacrifice time and money for it; without it, to attain the full measure of their growth would be impossible. Especially do country physicians need this association. The country physician with his large territory to cover, his necessarily general practice, can come very little into association with other medical men, and can have little opportunity or stimulus for original work.

In every intellectual pursuit, isolation is stagnation, and though the old-time country doctor of the good sort developed a kindly common sense and a quality of personal authority that were a saving power, the lesser men slipped from little knowledge to greater humbug without the saving grace of competition and inevitable discovery. Dr. Osler, in a recent address, speaking of hospitals, says: "The little farm well tilled is the best." It is with the most profound satisfaction that some of the country doctors connected with these small hospitals realize that in them and

through them they may obtain all that is best in their science.

Of course, it is impossible to have all the physicians of good repute of the community on the staff, but the relations of the staff to those not on the staff should be of so cordial and fraternal a character that all could, if they wished, be equally benefited by the hospital. The private rooms of the hospital should be at their disposal for the treatment of their cases, and they should be invited to all operations on ward patients when no objection is made by the patient. This condition does not prevail in all small hospitals, but in the Nassau Hospital, with which I am connected, the staff most cordially invite such co-operation with all physicians of good standing.

When such an association has been formed, the enthusiasm of the idealists is usually dashed when they find that for a building they are permitted to occupy any inadequate house whose owner can let it for no other purpose. However, obstacles strengthen the muscles, and a few years' healthy endurance will usually see a new hospital building projected. Here is the opportunity of the rural hospital; space and air are the great points of superiority of the rural over the city hospital.

A site must be chosen at a point most accessible by railroad and highway to the district to be reached, and as remote as possible from swamps, factories, and other contaminating agencies of air, earth, and water. The building-committee will journey through the regions of the impossible, and will then, if wise, emerge with a plan on the pavilion system, with wards of one story, separated by twice the height of each; well ventilated and lit by windows on at least two sides; better on three. The standard arrangement of wards will be followed; and a good practical operating-room, easily sterilized, must be planned. According to the resources of the hospital will be the administration rooms, matron's quarters, and nurses' rooms. They must be adequate; for good work cannot be continuously done without sufficient rest and relaxation. Heating, ventilation, store rooms must be provided for the economical and proper administration of the hospital.

So we have the rural hospital organized and equipped. Its use and success will depend upon the honest service it renders. The administrative details are the machinery; the better they work, the less grinding there is; but the reputation and prosperity of the hospital will depend finally on the real service it renders.

If the medical men give it their best, they will gain an enlarged capacity and an increased ease in their work; they will have the immense satisfaction of realizing that as far as the profession has gone, so far are they in real knowledge and in theory; and that most valuable adjunct of a medical man, personal quality, will grow, with exercise, to its fullest. As with the rest of humanity, the medical man shrivels with self-seeking, and reaches his largest growth in service to his kind.

There is still another service for the rural hospital to render its community. Little by little it should come to be the educational centre from which emanate modern ideas of hygiene. Farmers and dairymen should be encouraged to come to demonstrations regarding milk and water; popular talks on infection should be publicly given from time to time. With patience the hospital should in time come to see from its influence its country towns take pride in cleanliness; its country houses flushed with air and sunshine, and, possibly before the millennium, country cooking may present the aspect of simplicity and wholesome nourishment. This will not come at a bound, but must be one of the results of the hospital's winning confidence by its honest service and the loyalty that comes from the members of its committees and those pledged to its support.

The support of such a hospital must come from the people who, either personally or by report, come to know its value. Fortunately for the success of such an undertaking, the stress of city life is leading the very rich and substantially well-to-do to spend the greater part of the year upon their country estates. The success of this plan of life may be seen in the well-set-up, fresh-faced aristocracy of England, and its secondary effect, the personal interest that the gentry of England take in their local hospitals, is already shown to be the natural kindly outcome of such a centring of life in the country near our great cities. These quick brains see at a glance the enormous advantage of a well-built, well-run, local hospital, both individually and in its reaction on the doctors and the community, and often contribute generously in money, time, and care to its success.

To be substantial, the support of the home hospital must be an object of importance to all its neighbors. This applies particularly to churches, lodges, and also societies organized for charitable purposes. Committees should be appointed by these bodies to visit the hospital and gain accurate knowledge of its work and needs. Young peoples' auxiliary societies should be formed in the various villages; children organizing societies to utilize their enthusiasm for giving entertainments for the benefit of the hospital should also be thought of.

In one particular the rural hospital claims especially the attention of the city surgeon. It is the constant custom of physicians to send their convalescing patients to the country, that fresh air and quiet may do their healing work toward complete recovery. In cases of ordinary illness this is undoubtedly of great avail; but are there not many surgical patients whose recovery would be more speedily accomplished if they could have the benefit of these quiet and health-giving influences before their operations and while recovering from shock? Is it not worth the consideration of the professional brotherhood whether some mutually advantageous arrangement cannot be come to whereby surgeons would bring certain of their patients for operation to the neighboring rural hospital? It is easy to raise objections, more or less real, to this plan; but the serious question remains, Are there not patients who would distinctly benefit by such an arrangement? That the solidarity of the profession would be aided by such an interchange is beyond doubt, as is the stimulating effect on the local doctor. The strain would seem to fall upon the city surgeon; but the city surgeon of high repute shares the burden of other holders of treasure, and is usually willing to give himself for the good of his profession and the greatest interest of his patients. The real question then remains. Are the quiet and fresh air as potent forces for good as our general practice indicates, and if so, can the rural hospital practically co-operate with its city neighbors?

But without question there is one connection between the rural hospital and the city physician which is in every way desirable. Every city man has under his care from time to time a nervous patient, for whom he knows that proper care and quiet are the sole requisites for recovery. But this is not so easy to arrange as to prescribe: for the institutions to which such patients can go often regard them with a commercial eye, and benefit rather by their remaining than by their recovery. The interest and point of view of the rural hospital however, would be identical with that of the patient's physician. Here, then, seems to be one connecting link toward the desirable connection between the city hospital man and his country cousin.

The greatest good the rural hospital can accomplish

however, is among its own community. There, by its persistent demand for the best, it will in time educate its public till the common requirement will force even the casual medical man to a near approach to hospital standards.

X-RAY PHOTOGRAPHY.[1]

By EUGENE R. CORSON, B.S., M.D.,
SAVANNAH, GA.

The most important thing in *x*-ray photography is an apparatus which generates powerful *x*-rays, for it is both your camera and your sunlight; the rest of the process is easy enough. Unless you have an apparatus which can produce rays powerful enough to penetrate the bone itself, you can never get fine bone details in your skiagraphs, and your pictures will not be first class, no matter how skilful you may be in your photographic technique. I have seen much written about the great care necessary in carrying out all the steps in the photographic process, and the long and careful development of the plate, but unless the *x*-ray apparatus is a superior one, all the skill in the world cannot make up for weak rays, and what holds good in ordinary photography will not hold good in *x*-ray photography. In the ordinary plate exposure in a weak light, say, with the plate underexposed, all the points of the object or picture have at least had a certain exposure, which careful development may encourage and bring out; but with the *x*-ray, unless the radiation is strong, the bone is not penetrated, and certain important details have had no exposure at all, and cannot be brought out in the development, and I take it that a skiagraph which simply gives mere bone outlines is not first class, and should not satisfy the skiagrapher.

This being admitted, every effort should be directed, first, toward obtaining and working properly an efficient apparatus, and the rest will be easy enough. I shall, therefore, attempt in this paper to give the results of my own experience in this matter, so far as it goes, and to indicate the direction in which progress seems to be advancing.

I first began my *x*-ray work with a ten-inch spark coil, energized by eight storage cells, using on it the Apps vibrator, and the simple Queen tube. I got certain limited results, no matter how carefully my plates were treated, and they were turned over to a skilled photographer who had taken many prizes for superior work. I changed to a fifteen-inch spark coil, using on it the independent vibrator, and the self-regulating tube, the coil energized by twelve storage cells.

On first testing this coil I was greatly disappointed to find that I could not get a spark over ten inches from it, for I was under the impression that my *x*-ray intensity depended upon the spark length, and that a fifteen-inch spark was a third better than a ten inch. There was a great difference, however, in the character of the spark. In the first coil it was thin and intermittent, while in the new coil it was thicker, brighter, often multiplied, and quite continuous. Now, when I came to test the *x*-ray and photographic effects, I was rejoiced to find the greatest difference in my results. It was very evident that though the spark was no longer than in my first coil, the amount of current going through the tube was vastly more. The platinum became red more quickly, the tube would get hotter, there was a brighter cathodic illumination, and not only was the time of exposure of the plate much shortened, but I was getting negatives of greater brilliancy and sharpness, and a great deal of bone detail, no matter how thick the bone, provided it could be brought close to the plate.

This taught me that mere spark length was no index of *x*-ray efficiency, and that other factors had to be considered. The long spark heresy has had its day, or will soon have. Then came Wehnelt's invention which, by its great increase in the number of interruptions, also increased enormously the amount of current going through the tube, and with it a great increase in *x*-ray power as tested by the photographic plate, for by the fluoroscope alone the increased efficiency was not so apparent. Using the Wehnelt interrupter on coils of two-inch or three-inch spark length only, the increased current would melt the heavy platinum of the tube if continued for any length of time. It was, moreover, soon apparent that the Wehnelt interrupter did not increase the spark length, but that the difference was solely in the quantity of current going through the tube. Examine with a magnifying glass the photograph of the Wehnelt interrupter spark, and you can make out a great many individual sparks; in one I counted at least fifty. The valuable invention of Mr. E. W. Caldwell was in the same direction, and from what I can learn it is an improvement upon the Wehnelt model, though I have had no experience with it. However, the principle involved is the same; namely, by increasing enormously the number of interruptions there is a corresponding increase in the quantity of current, per unit of time, going through the tube, and a proportional increase in *x*-ray and photographic power. It should teach us the lesson that, in coil manufacture after a certain length of spark has been attained, every effort should be toward increasing the amperage, and up to the limit of the tube's endurance, and that a ten-inch or twelve-inch spark is certainly quite enough if your spark is a fat or multiplied one, that is, has a relatively high amperage. Mr. Elmer G. Willyoung, in a letter to me, writes:

"I have always felt the prime question of the design of coils to be the supply of a sufficient amount of energy at an E. M. F. great enough to break through. Excessive spark length in my opinion has nothing to do with the matter, and is in fact quite useless, inasmuch as the pressure at the terminals is bound to be cut down by reason of the tube resistance being lower than the full air-gap resistance which the tube replaces. As a matter of fact the average fifteen-inch coil being operated on a tube is not more than an eight-inch coil; usually not that. That is to say, the discharges that pass through the tube are not over parallel gaps greater than eight inches at the outside. Since now the total E. M. F. being generated must be the same (or practically so) as when the full spark gap without tube is used, it follows that the resistance of the circuit is only one-half, roughly, what it should be at full spark length and plain air gap. But the E. M. F. at the terminals of the tube is undeniably an eight-inch E. M. F. Hence the average fifteen-inch coil and the average tube is equal to an ordinary eight-inch coil giving out twice the amperage that such coil would ordinarily give. For as you know, the line of coils is generally designed to give the same amperage for every coil, the only difference being the E. M. F. Hence I argue, and this has always been my position, that the most valuable coil would be one designed for a suitable spark length, say eight inches or ten inches at the outside, but wound with a heavy wire so as to pass heavy currents. The difficulty from the manufacturer's point of view is that the 'big spark length' heresy is so rooted that it is almost impossible to shake it. Each succeeding man wants to outdo his predecessor; eighteen-inch coils and then twenty-inch, and here recently I hear of some one who is having a twenty-five-inch coil made. I have absolutely refused to make anything larger than the fifteen-

[1] Paper read before the American Electro-Therapeutic Association, September 27, 1900.

inch, except on the sole responsibility of the purchaser, nor have I been willing to assume any of the experimental expense, inasmuch as I have not cared to put anything of this kind on the market since I have no real belief in it."

With these inventions before us, and the evident direction that progress in technique has taken, I cannot understand that continued use by some of the frictional machine, in place of the powerful coil. The electrical excitation of the static machine depends upon the potential induced at its terminals, so that when used on a tube where the resistance and vacuum are low (the tube, by the way, best adapted for photographic work), there is not enough current generated, and although the spark gap in series with the tube, by increasing the resistance also increases the output of the machine, more energy is lost in the spark gap than is utilized in the tube. Even if you get a twenty-inch or thirty-inch spark it is too thin to do the work, it is *tensio et præterea nihil*, voltage and nothing else, and you do not get a sufficient quantity of current through your tube to produce the best results. My experience may be limited, but I have yet to see really fine skiagraphs of the more difficult parts of the body, with good bone detail, done with a static machine. The German authorities who have written for us the best works yet on *x*-ray technique—I refer especially to Donath [1] and Gocht,[2] only mention the static machine to condemn it. Donath's photographic work has been phenomenal, as he does an adult hip in twenty seconds, and he does it well. I can recommend his book most highly. It deserves an English translation to give it a wider circulation.

According to Donath, a soft tube of great constancy, and capable of a rapid taking up and giving out of great energy, is necessary for a negative of strongest contrasts; otherwise the heating of the tube through long passage of the current reduces its capacity even to its destruction. The use, therefore, of the intensifying screen (Verstärkungsschirm) accomplishes much, by shortening the time of exposure. He also insists that increasing the frequency of the interruptions in the coil likewise accomplishes the same result. It must be admitted that, for the proper exposure of the negative, a certain quantity of current is, or, let us say, a certain number of interruptions are, necessary for each case, and that the time of exposure is shortened in proportion as the number of interruptions increases.

Experiments with the Wehnelt or Caldwell interrupter fully confirm this. In skiagraphy their value is very great, though the danger of destroying the tube increases in proportion, and requires, therefore, very careful and very quick handling. This makes them useless for fluoroscopic work, as the time necessary here would quickly destroy the tube. Donath's experiments with soft tubes show that, unless there is a thick cathode and a strong backing of the antikathode, a blue light appears in fifteen to twenty seconds, and the tube is done for. This interrupter must, therefore, be regarded as unsuited for longer exposures, on account of this danger to the tube. Within certain limits, however, the reduction of the time is so great that the tube hasn't time to change its vacuum, and there is hardly a trace of warming in the tube from the strongest driving in the time necessary for the exposure, provided, of course, the antikathode is well backed. With the more difficult negatives of the pelvis which Donath was able to make in the laboratory of Dr. Wehnelt, at Charlottenburg, the conditions were less favorable, at least for soft tubes, which, at the end of an exposure of twenty seconds, showed a tendency to "go under," with the characteristic blue light. While he did a pelvis of a thirteen-year-old boy in seven seconds, the pelvis of an adult woman required a rated exposure with a medium hard tube, constant for the first few seconds, but becoming soft at the end of the exposure.

I have introduced this experience of Donath to show that increased interruptions increase the amount of current through the tube, increasing at the same time the *x*-ray and photographic efficiency, although, unless we modify our tube construction, the new interrupter may be too much of a good thing, and that for safe working the interruptions must be decreased. I am inclined to think that Mr. Caldwell's model is a more practical instrument and can be more easily regulated and handled, although, as I have said, I have had no experience with it.

As we can measure quantity of current by electrolysis and chemical reaction, so, I believe, the amount of chemical change in the silver salt in the photographic plate is also an index of the amount of current going through the tube, and the difference in the photographic effects of high and low vacua is simply the difference in the quantities of the currents in the two instances going through the tube, and this difference must be considerable. Progress in *x*-ray efficiency must be along this line; in fact, it is already well started in this direction, for the real improvements have been in coil construction, and rapid interruptions, and stronger tubes to stand the increased currents, and it is very evident that we have not yet reached the limits of human endeavor in this direction. We shall have better coils, better interrupters, and better tubes to meet the greater strain.

Using the Queen independent vibrator, I always work it to its highest point of interruptions, removing the bob from the spring to accomplish it, and straining the spring so that I frequently break it, having always a new one ready for the emergency. In this way, with my coil I imagine I get an approach to the Wehnelt effect. I have to use a tube with an extra thick platinum. In the ordinary Queen tube I have melted the glass insulation close up to the platinum reflector, and reduced my vacuum almost to destruction.

The Queen independent vibrator, if modified in certain small details, to facilitate the replacing of the spring, I regard as altogether the best interrupter at our disposal, and although it cannot give me the very short exposures of the Wehnelt interrupter, my tubes live longer and are not destroyed, and the difference to the patient skiagraphed amounts to nothing; for one desirous of having his hip properly shadowed does not mind an exposure of five to ten minutes.

The Queen self-regulating tube I must also regard as the best attainable, with present views on tube construction. I have one I have been using two years, and it is still a good tube. My experience with other tubes has not been anything like so favorable.

To recapitulate briefly this part of my paper:

A change from a coil giving a thin ten-inch spark to a coil giving a very fat and multiplied spark of ten inches produced startling differences in my photographic results. With the former coil, although my plates were developed by a skilled photographer, the results were ordinary, while with the latter coil the first plate from it which I developed myself, without any previous photographic experience, gave me a negative of great brilliancy and fine detail. The difference was the amount of current going through my tube. The time of exposure and the time necessary for developing were both shortened—with the old coil it took thirty minutes to get an ordinary hip, while with the new coil it took eight minutes, and I got, moreover, a negative which brought out the parts more clearly and

[1] "Die Einrichtungen zur Erzeugung der Roentgenstrahlen und ihr Gebrauch." Von Dr. B. Donath, Berlin, 1899.

[2] "Lehrbuch der Röntgen-Untersuchung zum Gebrauche für Mediciner." Von Dr. Hermann Gocht, Stuttgart, 1898.

with more detail, and, if I used a fluorescent screen, I got the same hip in one and a half minutes, though by this method the outlines are never so sharp. If Prof. J. J. Thomson and Sir George G. Stokes are correct in their theory of the nature of the *x*-ray, namely, that the radiation is a series of electric impulses given out from a point on the platinum reflector where the charged molecules strike with great velocity, and give up their charges — and in my humble judgment their writings are more worthy of credence than any I have seen—then, I think, it must follow that the heavier the current going through the tube, the heavier the charges on the molecules, and the greater their velocity, the more powerful the *x*-ray effects. Be this as it may, and however beautiful the theory, my own experience compels me to put down as the first and most important desideratum in *x*-ray work, the employment of a coil of moderate spark length, say ten or twelve inches, so wound as to give a large quantity of current in the secondary, and with all the current going through the tube which the tube can stand, which means the use of a high order of interrupter, like the Caldwell or the Wehnelt, or the Queen independent vibrator.

Using the heavy current, a proportionately lower vacuum is practicable, and the photographic effects are greater. In other words, within certain limits, with any stated vacuum, its penetrative power is increased by increasing the quantity of current. Always use, therefore, the lowest vacuum which will penetrate the parts.

In my own work I have endeavored to bring out the bones with all the internal structure possible, on a white background, with the flesh and the superficial details wiped out; in other words, I wipe out the non-essential parts and bring out the bone with all the contrast possible. Most of the skiagraphs which have come to my notice have not carried out this idea, for the flesh is still in evidence, and the printing papers employed are not the best adapted for strong contrasts. It is easier for the imagination to supply the flesh to the bones than to leave the bone details to the imagination. It is the bones we are after.

I secure absolute immobility of the part skiagraphed by binding it firmly to the plate and by placing a heavy weight on the limb to prevent even any movement from the arterial pulsation. The heavy weight accomplishes two things, it presses the bone as near the plate as possible, a most important requisite, and it also, as I say, prevents any possible movement from the pulse. This is all done in a way to make the patient as comfortable as possible. In choosing the side which is to be against the plate, select that which brings the bone the nearest to the plate, for the closer to the plate the sharper the outlines and the better the internal detail. The proper exposure must vary with each apparatus, and has to be learned after careful trial. I believe that, usually, plates are underexposed. I judge so from the prints and from the accounts of long development. There is a common belief that *x*-ray plates all require a very slow development. Some of the best plates I have ever had have come out almost as rapidly as the ordinary photographic plate. My own experience is that three to five minutes is quite sufficient, and when the plate takes longer it has usually been underexposed. If the *x*-ray is weak and the bone itself has not been penetrated, there can be no bone details, no matter how carefully the plate is developed for there is nothing to develop; the *x*-ray plate is entirely different from the ordinary underexposed plate, for here all the detail has had at least some exposure which can be brought out.

I have tried about all the developers, and have come to regard the hydrochinon as perhaps the best. I seem to get deeper, denser, and more brilliant negatives from it, while the detail is just as good as with the metol. I use for convenience the hydrochinon powder. I wash the plate two hours, following Carbutt's advice, using also his formula for the fixing with the chrome alum.

The plate is always intensified, no matter how strong the negative is, for otherwise some of the flesh will come out in the print. The intensification is so strong in some of my plates that they have to be held up to the direct sunlight to make out the detail, and the printing on "velox" paper has to be done in daylight, and even then requiring one or two minutes' exposure. In intensifying I use Carbutt's formula of one-half ounce of corrosive sublimate and one-half ounce of ammonium chloride in twenty ounces of water. The plate is washed again for half an hour. A solution of ammonium chloride, one-half ounce in twenty ounces of water, is flowed over the plate for half a minute; it is washed again for five minutes, and then immersed in an ammonia solution, two drachms of aqua ammoniæ in one pint of water, until black. It is then washed again for five minutes, and dried.

Such a negative will print out on "velox" paper, without any flesh, and with a fine black-and-white contrast.

There is often great difficulty in getting the "velox" print from a highly intensified negative, on account of the great difference in different parts of the negative, due to the different thicknesses of the parts skiagraphed, certain parts being overexposed while others are underexposed. This can be largely overcome by passing the hand rapidly to and fro over those parts which require less exposure, or by using a shaded screen. Again, it is often very difficult to print in certain fine details without getting the rest of the print too dark. For example, in a sagittal view of the knee, the patella will have to be printed separately first, before printing the rest of the negative, and, being some distance from the great bones which form this joint, this can easily be done.

Even in the hip joint almost all the flesh can be wiped out if the negative is a strong one, and has been, in addition, strongly intensified. I have found that the "carbon matt velox" is by all odds the best, as being less sensitive than the "special velox," a very necessary quality when we are striving to get the bone on a perfectly white background.

Although the "velox" print is a difficult one to make, and you will have to throw away many a print, when you do succeed you have a beautiful picture which will be easy to reproduce in your publications. I must admit that, in printing large negatives, seventeen by twenty inches, I have used "solio," but had I to prepare for publication such a print I should still use the "velox," despite the labor and loss it might entail. In my skiagraphic study of the normal membral epiphyses at the thirteenth year,[1] I have had a carpus enlarged two and a half times to show what can be done in the way of preparing large skiagraphs for use in the laboratory and the lecture-room. If your original negative is fine, you can get beautiful skiagraphs which make the internal detail even more evident, though the outlines may not be so sharp. I show you a carpus, an elbow, and an ankle so treated, and the effect seems to me to be fine. You get the bone designs drawn for you in strong lines—a charcoal drawing on white paper. In this process a positive is taken from the intensified negative and from the positive the enlarged negative, which is again intensified before printing from it. For diagnostic purposes the fluorescent screen of potassium platino-cyanide, the Verstärkungsschirm of the Germans, is a most valuable addition to your *x*-ray outfit, especially when you have a very thick part to skiagraph. This salt gives a bluish light and acts with greater rapidity on the photo-

[1] Annals of Surgery, November, 1900.

graphic plate. The time of exposure is greatly shortened — about one-fourth the time being necessary. The outlines are not so sharp, but a greater drawback is apparently unavoidable spots in the screen, due seemingly to a lack of uniformity in the coating. In the negative these come out as bright spots, which will have to be gone over very carefully to print well from. When our aim, however, is a correct diagnosis, this fault is trivial. With a screen made for me by Ernecke, of Berlin, I get an ordinary hip in one and one-half to two minutes.

A field of usefulness for the *x*-ray which has not yet been thoroughly worked up, and which I am sure promises much in the future, is the study of normal osteology and bone development, and, in my skiagraphic study of the normal membral epiphyses at the thirteenth year, I have attempted to show what the *x*-ray can do for us here. It is especially in this line that enlarged skiagraphs, suitable for the laboratory or the lecture-room, will prove most instructive, as giving in strong, bold lines the internal bony structure along with their outlines, and, most important of all, in their exact spacings and relationships. I show you these three enlargements to give you an idea of what may be accomplished in this direction. I have found that there is but one way to accomplish this properly; namely, by first making a positive, and from this taking an enlarged negative, which is again intensified before printing from it.

The direct enlargement on bromide paper from the original negative, though a much shorter and simpler process, does not yield as good results, on account of not eliminating the flesh, and you cannot, therefore, get the bones alone on a white background. I show you an elbow, enlarged by the bromide process, and although the details are fine, the general effect is not so striking as in the longer process of positive and enlarged negative.

Since reading the above paper before the American Electro-Therapeutic Association, I delivered a lecture at Cornell University on my *x*-ray study of bone development, and my "velox" prints were rephotographed for transparencies for the stereopticon. There can be no better test of a printing paper than this, for they came out on the screen with all the detail and contrast magnified. A good skiagraph, when printed out without any flesh, lends itself admirably to this mode of exhibition, and can be made most instructive. I have long felt that the *x*-ray would prove most valuable in anatomical study and demonstration, and this test convinced me of its great utility. I refer the reader to my paper in the *Annals of Surgery* for November, where these plates have been reproduced, and though the plates are inferior to the original "velox" prints they are sufficiently good to show what can be done in this line of work. It is the fine black-and-white contrast—and without any sacrifice of the detail—which makes the "velox" paper so well adapted to this form of photographic work. I am convinced that the black on the white is better than the white on the black when the prints are made from positives, as carried out in a recent German atlas[1] which has come to my notice. Beautiful as this atlas is, I believe it would have been more effective if printed from negatives instead of positives.

Oxyurides.—Rid the rectum of fecal matter by means of a full injection. Then inject a two-per-cent. solution of nitrate of silver, to be left in for five minutes, and then the excess is neutralized with salt solution. —De Guy.

SOME FACTS OF RESPONSIBILITY IN SPIRIT AND DRUG TAKERS.[1]

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.,
SUPERINTENDENT WALNUT LODGE HOSPITAL.

A crime is committed by a person while under the influence of alcohol or drugs; a will is written while the person is using spirits to excess; an important contract is made and signed in this same condition; a course of criminal conduct is followed, and the actor is using spirits or drugs constantly to excess.

Such cases come into court. The counsel turn to the physician for help. There is some abnormality in each instance. The acts are without the pale of reason, and the continuous use of spirits clearly disturbs the natural common-sense line of conduct of the person. The lawyer turns to the rulings of judges in similar or allied cases, and the physician to text-books of medicine and medical jurisprudence. Both fail; and while the lawyer finds rulings that apparently apply to such cases, he is conscious that they do not comprehend or recognize the real facts at issue. The more closely he studies these facts, the wider seems the discrepancy between them and the theories of the law. The judge recognizes this inconsistency, but is forced to follow lines of previous rulings, and only along certain narrow limits dare he venture to express opinions at variance with other judges. The legal theories of these cases are the outgrowth of the moral teachings of past centuries. These teachings are that inebriety is but a development of the moral depravity innate in every life, always ready to grow and develop, and particularly ready through wilful neglect and gratification of the lower animal instincts; also that inebriety is always a phase of savagery or an inborn tendency to lawlessness, giving up restraint and control, indulging all the passions regardless of society or the interests of others. The remedy is punishment, involving pain, and in this way building up the moral to control the lower animal.

Dogmatic statements and theories, that are obviously unsound and in conflict with the fact, comprise the largest part of so-called authorities on this subject. The physician turns to a study of the cases, and seeks to find out the facts as they are presented in real life. Here a new world of truth confronts him. The inebriety of the prisoner or the person in question is found to be due to a physical condition that is both inherited and acquired. This physical condition is literally a disease, and is practically an obscure or pronounced form of insanity. In some cases the drink craze is a symptom of insanity. When the symptoms of a large number of cases are studied and compared, they are found to follow a uniform line of origin, progress, and development.

Tracing the effect of alcohol on the system, one perceives that its continuous use in excess at intervals, is always followed by degrees of brain and nerve palsy, paralysis, congestion, and impaired and diminished activities. Alcohol in the system to excess is always followed by incapacity of the senses and judgment, with lessened power of control. The degree will vary widely with the amount taken and the state of the health, but impairment and disability is a physiological consequence, to which the exceptions only prove the rule.

The legal theory on which the present administration of the law is based, assumes sanity and sufficient mental soundness to act rightly. The remedy for contrary conduct is more severe punishment to awaken a sense of accountability.

Practically, this theory presupposes a degree of

[1] Read before the Pan-American Congress, Havana, February 5, 1901.

psychological knowledge and a capacity to distinguish lines of health and disease that is far beyond any present attainments of science. The conclusion from a medical study of these cases is that every case is one of physical degeneration and progressive disease. The correct medical jurisprudence of inebriety would embrace, first, a question of the facts in each case, and their meaning—facts of heredity, of growth, of culture and health; facts of disease, of injuries, of degenerations, local and general; of the influence of surroundings; of occupation and climate; and all the history, physiological, pathological, and psychological. From these facts only can any clear, intelligent conception be formed of the act and its motives. When this can be settled, then the legal question of what shall be done, and what disposition will more accurately serve the cause of justice, will appear. The legal punishment of inebriety theoretically aims to check and prevent illegal acts by inebriates. But practically and literally the very opposite effects follow. Experience of all the courts in this country and Europe proves that capital punishment for murder committed by inebriates never deters other inebriates from committing similar crime. In this diseased, mental condition they are more often incited to commit similar offences by the recital of crimes of violence. Notwithstanding this fact, inebriates are tried and executed daily all over the country.

Fines and imprisonments for illegal and criminal acts are not only absolutely worthless as deterrents, but increase the very conditions which they are intended to check.

The physiological fact in these cases is that legal penalties, which are supposed to appeal to the higher moral brain, make no impression; for the reason that the higher brain is so impaired and palsied that it cannot recognize or respond to these influences.

The question of the legal responsibility of a man charged with the commission of a crime, in any given case in which spirits have been used before and during the act in question, must be decided from a study of the mental health of the man. If there is a reasonable doubt of mental soundness at the time the act was committed, the degree of responsibility will be lessened. If there is evidence of delusions, or strange unusual beliefs which influence conduct and warp judgment, or if his mind acts in an impulsive, unreasoning way, apparently under an irresistible impulse, incapacity is an established fact. The question of capacity to distinguish between right and wrong in all these cases is difficult to decide.

The immediate effect of alcohol is to obscure and break up the power of discrimination between right and wrong.

The use of alcohol is always followed by an increase of the heart's action, and later, a corresponding diminution of the flow of blood. This increased heart's action is followed by unsteadiness of brain force and activity. The increase of the heart's action extends to all parts of the body, giving the appearance of greater power; then, after a time, there is lessened power and energy until stupor comes on.

In all men who use alcohol there occurs this alternation of exhilaration and depression; and when this is repeated for years, positive damage follows. First of all, the senses become impaired; and this condition always darkens knowledge and misleads the judgment. This follows from the fact that accurate perceptions are wholly dependent upon definite and normal sensations. When the senses are disturbed and impaired, perceptions are correspondingly disturbed; they are unable to present the facts to the mind as they really exist in the surroundings.

The fine shadows, the uncertainties and doubts which attend many human transactions, escape the notice of the inebriate; hence he imagines they do not exist. The more alcohol he uses, the more positive things appear; they have the quality and energy of absolute demonstration. He never doubts or hesitates. Such a man is a dangerous witness in criminal courts, through his defective knowledge, and because he has a morbid positiveness that often carries conviction. In reality an inebriate witness testifying to events observed while sober is more reliable than a sober witness testifying to events observed while intoxicated.

The inebriate state is one of anæsthesia, manifested by the rude grasp of the hand, a loud voice, and a certain exaggeration of manner, as if the one affected were trying to assure himself of the reality of his senses.

The senses of touch, of sight, of hearing, of smell, and the muscular sense all show disturbance and point to a degree of paralysis, which manifests itself in illusions, hallucinations and perversions, impeded articulation, staggering gait, and diminished functional and organic activity. This is literally in a degree paralysis, and weakens the control of volition. No effort of will can remove or lessen these incapacities from alcohol. Weakness, prostration, and debility respond in some measure to the calls of volition, but paralysis from alcohol, never. Hence the responsibility of the inebriate is lessened and differs from that of all other narcotic states, in direction and degree.

It can be readily seen how impossible it is for the mind to receive accurate knowledge of events and persons exterior to it when this degree of paralysis extends to the higher operations of reason and co-ordination, in which both the facts and the conception of them are faulty and perverted. The co-ordinating brain centres are enfeebled, and cannot analyze the impressions of the senses, and this extends to those higher operations of the brain, called morals. The paralysis of the lower ranges of brain activity quickly dulls and breaks up those fine distinctions of duty and the consciousness of right and wrong. It is a physiological law of growth and development that the highest elements of brain activity and power are formed last. This is called the character, the "morals" of the man, and from the use of alcohol it appears to be the first to suffer and be destroyed.

The inebriate, like the man intoxicated, exhibits confused, halting ideas and beliefs about morals and his duties to his fellow-man. His ethereal sensibilities and conceptions of duty and obligations undergo a progressive degeneration, while the coarser organic operations of the mind and body seem but little disturbed. Hence the acts and thoughts that are supposed to be malicious and brutish indicate merely a suppression of the higher co-ordinating centres. This is seen practically in many cases in which persons of refinement in thought and act, after the use of alcohol have become coarse in language and manner, and brutal in conduct. Often the inebriate is amazed when told what he has said and done while under the influence of alcohol, showing how far he has been dominated by the alcoholic paralysis. But if the drinking is continuous, he is unable to review his thoughts and acts, and both the mind and body undergo a debasement that is marked. Morally, mentally, and physically, he slowly or rapidly grows crippled and deformed. The inebriate is a moral paralytic. His intellect is disordered, and among the insane none are more dangerous, for the reason that he has no fixed mentality or conception of himself and his relations to others. He may, before the use of alcohol, have formed habits and conceptions of life that cling to him automatically, and thus enable him to act in the ordinary grooves of normal life, for a while, without

marked debasement. He may, as a professional man or as an artisan or farmer, pursue his vocation with reasonable success; but let some supreme crisis intervene, let some emergency throw him out of his automatic range of life, and his true state will be revealed. His damaged brain may be seen either in crime or the insane confusion of all his thoughts and acts.

Beyond all question, these results are caused by alcohol alone; and its effects on the brain and nervous system are anæsthetic and paralyzant. The heart, the senses, and then the higher brain centres slowly succumb to paralysis, while the victim's capacity to realize his true condition and adjust himself to it grows less and less. His conception of right and wrong, of duty, of obligation and responsibility, grows more and more confused. The victim may for a while perform his daily routine in accordance with his surroundings, but he is a mere mental waif, drifting at the mercy of his surroundings and the uncertain conditions of life.

The fact I wish to make prominent is not the legal irresponsibility of these cases, but that the present legal standard is wrong and contrary to all the teachings of science. The superstition that insists on full measure of accountability in all cases in which spirits are used, and assumes that the use of alcohol is a voluntary act of the brain, both conscious and capable of control, is a sad reflection on the intelligence of the present age.

The interpretation of the law that boundary lines of responsibility and irresponsibility can be marked out in case of inebriety is a delusion. The effort to find a dividing-line where sanity and insanity join, or where the brain could or could not have controlled its acts or realized their nature, is an impossibility. The strange theory which seems to be fixed in the legal conceptions of inebriety, that alcohol can be used to excess at intervals or continuously, and the person retain the full possession of his faculties and have the same power of control as in health; also that no history of excessive use of spirits before or during the commission of the act has any bearing on the case, unless associated with marked symptoms of insanity, are all errors that make justice impossible in these cases.

To-day a large percentage of all medico-legal cases is associated with inebriety, and the legal responsibility of inebriates is decided from theories formulated centuries ago. The real responsibility and accountability in these cases is very different from the conception of them formed in courts of justice.

The teachings of modern science open up a new world of facts that indicate clearly the physiological nature of all brain activities; facts that show the influence of heredity, of injuries, of strains, of drains, of failures, of diet, of surroundings, of culture, of ignorance, and all the vast ranges of influences and forces which enter into the acts and character of every person.

It is from this evidence that the questions of responsibility and capacity to act sanely at any time and under any circumstances can be solved. No legal responsibility in inebriety can be solved from any other point of view or other theories. It is a pure question of facts—not theories of law or rulings of judges. What is the history of the man and the act in question? Ascertain these clearly, and the problem is solved. Fail to do this, and confusion, injustice, and wrongs follow. The legal responsibility of inebriates, as determined by courts to-day, is a farce. A new jurisprudence is demanded. A new scientific study and recognition of the facts in the cases of these inebriates and their disabilities are called for. This need is felt in every court of justice by clear and thoughtful men.

AN UNUSUAL CASE OF PARTIAL RECOVERY FROM EMBOLISM OF THE ARTERIA CENTRALIS RETINÆ.

By EDGAR S. THOMSON, M.D.,

NEW YORK.

Cases of partial recovery of vision after embolism of the central artery of the retina, while rare, have been observed and described by several writers. The following case is unusual, so far as I know, in the extent of recovery. I am indebted to Dr. Webster for the first part of the history. His notes, in part, are as follows:

October 4, 1895. M——, banker, aged fifty-nine years. Last evening he was reading and got up to light a cigar. When he sat down again he found that he could not read and, feeling a fulness in his left eye, he covered his right with his hand and found he could not see at all with his left, except at a little margin at the upper and outer corner. R. V. = $\frac{20}{40}$ +, with correcting lens. L. V. = fingers at 2 feet in superotemporal periphery.

Ophthalmoscopic examination: Embolism of the central retinal artery. The descending artery is nearly obliterated, the ascending much reduced in size; above the disc is an area of thin exudation. The macular area is reddish, but not "cherry" red, and there is a large, pale, soggy-looking area.

Treatment: Blue glasses, and strychnine gr. $\frac{1}{60}$ three times a day.

October 7th. L. V. = $\frac{8}{200}$, in superotemporal periphery. The descending artery begins to fill a little. The area above the macula is more milky. I gave, in addition, bichloride of mercury gr. $\frac{1}{32}$ twice a day. He has a mitral regurgitant murmur and the urine contains hyaline and epithelial casts.

October 9th. The patient sees objects down to the centre of the field. L. V. = $\frac{10}{200}$.

October 21st. L. V. = $\frac{20}{200}$ (superotemporal area).

When I saw him, April 8, 1898, his vision was nearly normal in that eye in the upper half of the field. My record of that date was: R. V. = $\frac{20}{200}$: $\frac{20}{30}$ W. + 5 D. s. L. V. = $\frac{20}{200}$: $\frac{20}{40}$ W. + 5 D. s. (in the upper half of the field). The entire upper half of the field was restored down to within ten degrees of the macula. There was no perception of light at the macula nor in the lower half of the field.

With the ophthalmoscope, the upper part of the retina appeared slightly atrophic, finely stippled with pigment, and the vessels reduced to mere threads. The upper half of the nerve was white. The lower half of the nerve was normal in color and there were no pigment changes in the lower half of the retina. A row of six large arteries could be seen springing from the lower edge of the disc and running down over the lower half of the retina. The patient lived for nearly a year after this, without further loss of vision, so far as I know, and died suddenly of heart disease.

At the first glance one might have thought that these were cilioretinal arteries, but the fact that the vision was primarily reduced in the area supplied by these vessels shows conclusively that they were branches of the central artery. Cilioretinal vessels spring from the anastomosis around the nerve known as the "circle of Zinn," and when one of these is present in an eye affected by embolism the area of the retina supplied by it is unaffected from the start. There is usually but one cilioretinal vessel and it most commonly springs from the temporal side of the disc and courses over toward the macula.

Microscopical examination has been made in several cases and the existence of the cilioretinal vessel demonstrated (vide W. Adams Frost: "The Fundus Oculi," p. 52). In any normal eye, however, we can infer that a vessel comes from the circle of Zinn only by the sharp hook-like turn it makes as it leaves the

disc. Very frequently the central artery of the retina bifurcates and gives off branches in the substance of the nerve, and undoubtedly this was the condition in the case reported. The embolus was dislodged within a day or two and driven onward into the superior branch, before the lower part of the retina had had time to atrophy.

In cases of embolism modified by the presence of a cilioretinal vessel, atrophy of the nerve is apt to follow, and the eye becomes totally blind in all parts of the field. This was the case in an eye observed by W. Adams Frost ("The Fundus Oculi," plate xli.).

The fact that total atrophy of the nerve had not occurred in the case under discussion, three years after the embolism, further indicates that the vessels were branches of the central artery.

When the embolism is far enough back to cut off the whole artery, atrophy of the nerve is almost certain to follow, as in the case examined microscopically by Marple (New York Eye and Ear Infirmary Reports, January, 1895), while if the embolus moves forward to the level of the retina, optic atrophy is not likely to occur. The attempt has been made to cause the embolus to move forward into a smaller branch, as occurred spontaneously in the present case, by performing a paracentesis corneæ, with the hope that the reduction of tension would allow the pressure of the blood current to dislodge the embolus. Schmidt-Rimpler advises massage of the nerve by passing a strabismus hook back through the orbital tissues and hooking the optic nerve, when it can be massaged gently by passing the hook backward and forward. He cites one case in which he succeeded in restoring good vision by this procedure. Unfortunately, however, these methods have been almost uniformly unsuccessful in the hands of others. When there is nothing to lose and much to gain, the attempt is certainly justifiable, but of course, after a day or two, the embolus has become adherent to the vessel wall, the retinal degenerative processes have begun, and no treatment can be of use.

16 East Forty-third Street.

Experimental Work in Hepatic Hæmostasis.—Luigi Baldassari carried out his experiments on rabbits and dogs. Under chloroform anæsthesia the animal's abdominal wall was opened, and a deep wound was made in the convex portion of the hepatic lobe selected, which bled very freely. The margins of the wound were then separated, and a piece of decalcified bone was introduced and sutured in place, exercising a certain amount of pressure. The abdominal walls were then sutured and the animal was allowed to recover consciousness. After a time, varying from a few days to a month and a half, the animal was killed, and a careful examination made. Hæmostasis was in every case found to have been perfect, and the wound completely healed. Forty-five days after the operation the bone was found to have been absorbed, leaving only a faint grayish line on the hepatic tissue.—*La Riforma Medica*, February 21, 1901.

Bloodletting in Pneumonia.—Corradini Rovatti reports a case in which bloodletting gave immediate relief to the patient, causing a diminution in the sharp pains at the base of the left lung, causing the pulse to become strong, full and more rapid, and lowering the temperature from 40° C. to 38° C. A deep and refreshing sleep followed the procedure, and although the patient remained in a condition of weakness for several days, he was practically cured by this measure. Bloodletting overcomes passive congestion with the cyanosis, dyspnœa, etc., attending it, and also in infective diseases of the respiratory tract eliminates a large part of the toxic substances from the circulation. It also brings relief to an overworked heart, facilitates breathing and oxidation, and increases the elimination of urine. In all cases of pneumonia in robust subjects, bleeding should be practised.—*Gazetta Medica Lombarda*, February 17, 1901.

Some Unusual Symptoms in Typhoid Fever.—Umberto Baccarani writes in detail of these symptoms seen in several cases, which, briefly stated, were: Delirium and insomnia in the prodromal stage; enterorrhagia at as early a period as the fifth day of the disease; the palmo-plantar symptom, or yellow coloration of the palms of the hands and soles of the feet; the *pulsus paradoxicus* disappearing during inspiration and reappearing with expiration; splenic cough, produced by palpation of the spleen; salivation; urethritis; desquamation, and finally, pruritus. The author calls attention to a point in the treatment, namely, the administration of small enemata of boiled water during the early days of constipation, to remove fecal accumulations which probably cause a slight rise of temperature.—*La Riforma Medica*, February 23 and 25, 1901.

Chronic Purulent Otitis Media.—G. Ostino says that there is not simply one disease known as chronic purulent otitis media, but there are various forms of the affection, each one of which may require a different treatment, according to the degree of the lesion. Conservatism should be the rule wherever possible. Macewen's advice to open the mastoid cells even in cases that could be treated through the auditory canal, because asepsis of the middle ear is impossible, was refuted by the aural surgeons at the International Congress in London, 1899, who reported hundreds of recoveries either by medical antiseptic or caustic treatment, or by operations of a simpler nature, such as extraction of the malleus and incus, atticectomy, scraping the bone, etc., in cases in which Macewen would have operated.—*Giornale Medico di Regio Esercito*, February 28, 1901.

The Healing of Cerebral Abscesses.—Passow records the case of a man in whom an acute otitis had caused a mastoiditis and the formation of a perisinous and a small cerebral abscess. As frequently occurs, the symptoms were insignificant compared with the seriousness of the disease. Even the extensive destruction in the mastoid process could not be diagnosticated with certainty before the operation. Only the irregularity of the pulse aroused the suspicion that the process had reached the cranial cavity. The cerebral abscess itself had not caused any conspicuous symptoms, as it was only in its incipiency. The course of healing was extremely favorable. The discharge from the brain abscess ceased on the second day. While still in the hospital the patient developed depression with hypochondriasis, and committed suicide seventy days after the operation. Previous to death he had contracted a fresh otitis, leading to mastoid trouble, and the latter was operated for in the usual manner. At the time of his suicide he had been discharged from the hospital, and was being treated as an out-patient. Autopsy revealed the following conditions in the brain: The skull cap was thick and the dura in several places adherent to the bone. In lifting the brain a piece the size of a large pea remained attached to the tegmen tympani. This left a defect in the brain, from which a barely visible cicatrix, 1.5 cm. long, without pigment, softening, or fibrous tissue, could be traced into the brain substance. On detaching the dura from the tegmen tympani the opening made by the operation was recognized and found filled with loose cicatricial tissue. The gauze in the mastoid wound was impregnated with serous but not with purulent secretion. Careful examination of the mas-

toid nowhere revealed diseased bone. The wound had closed considerably. The middle ear was in normal condition. The fact was noted that the tegmen tympani on the healthy side was exceedingly thin and cribriform. Incidentally, a small lenticular osteoma with sharp, notched edges was found in the falx cerebri.—*Archives of Otology*, vol. xxx., No. 1, February, 1901.

Static Electricity in Medicine.—Augusto di Luzenberger concludes a long study of the subject by saying that the matter has not been thoroughly understood by the majority of writers, who are inclined to attribute a purely suggestive value to electricity. Those who possess good electrophores and have used them methodically in treatment, carefully observing the results, not simply contenting themselves with a haphazard application, are fully convinced of the therapeutic value of the procedure. This consists of stimulation of the nutritive exchanges, and in certain modifications of circulation and secretion. There is also a stimulating trophic action on the tissues of the organism. To attain good results, however, the practitioner must be familiar with his machine, understanding exactly the strength which he is using and the various ways of modifying it to obtain desired effects. In short, the scientific precision used in galvanic applications must be used in the applications of static electricity.—*Giornale Internazionale delle Scienze Mediche*, February 15 and 28, 1901.

The Relationship between Chronic Renal Disease and the Condition of Excitement and Depression in the Insane.—W. B. Gow finds: (1) That granular kidneys are more frequent in the insane than in the sane. (2) That in the insane they do not give rise to the usual physical signs and symptoms. (3) That the frequency has a distinct connection with the mental condition of the patients. The condition favoring the occurrence of granular kidney is that of motor excitement. (4) That a low blood pressure is found in similar cases, whereas in melancholia and delusional insanity the blood pressure is raised. In these latter a normal or merely congested condition of the kidney is found. (5) That in general paralysis the kidneys are sometimes granular, sometimes congested, but they probably vary with the condition of the blood pressure, which has, up to the present, not been satisfactorily investigated. (6) That the cause of the lowered blood pressure, or the lowered blood pressure itself, is probably the real cause of the increased frequency of granular kidney in cases of motor excitement.—*New Zealand Medical Journal*, February, 1901.

Report of a Case of Pylorectomy for Carcinoma.—Stuart McGuire reports a case in which the malignant growth began in the pyloric valve and extended about four and a half inches in the walls of the stomach. The diseased portion was excised, care being taken to cut through apparently healthy tissues at least one inch from the neoplasm. The divided end of the stomach was then united from above downward with three rows of silk sutures until an opening was left only at the inferior angle equal in size to the lumen of the cut end of the duodenum. An anastomosis was then effected between the two by means of a Murphy button. The patient made a good recovery. Six weeks after the operation he is improving steadily in weight, has a good appetite, sleeps well, has regular movements from the bowels, and is getting strong rapidly. Maydl, reporting twenty-five cases, states that sixteen per cent. of the patients died from the operation, twenty-eight per cent. from recurrence, and fifty-six per cent. are still living. One patient operated on in August, 1890, still lives. This good showing is undoubtedly due to better technique, earlier recognition of the presence of cancer, judicious selection of cases, and experience.—*The Clinic Bulletin*, January–February, 1901.

Pyelitis from Eberth's Bacillus.—Carlo Comba reports the case of a child who was suffering from typhoid fever. The acute stages of the disease were passed and the patient seemed on the way to recovery, when a new group of symptoms appeared, consisting of a sudden rise of temperature, intense and persistent pain in the right lumbar region, radiating to the pelvis. This condition lasted eight days. An examination of the urine revealed acute pyelitis of the right side. Eberth's bacillus was found in large amount in the urine. The treatment consisted of milk diet, baths at 32°–34° C., strophanthus, caffeine, Sangemini water in great quantity, and salol. During convalescence daily injections of 1 mgm. of nitrate of strychnine were given.—*Rivista Critica di Clinica Medica*, March 2, 1901.

Retroflexion and Retroversion of the Pregnant Uterus.—H. Keitler reports some case histories which lead him to conclude that retrodisplacements of the pregnant uterus are caused not only by impregnation of an already retroflexed or retroverted organ, but may also be the result of changes in the position of a gravid anteflected uterus. The two forms of malposition may at first be interchangeable and the deformity may become definitely fixed as one or the other only, after persistence of the retrodeviation. The prognosis of the two conditions is also somewhat different and attempts at accurate diagnosis are therefore always indicated, since there is no hope that a retroversion will ever spontaneously correct itself, whence active therapeutic measures should be instituted early, though even in retroflexions an unassisted cure should not be counted on.—*Monatsschrift für Geburtshülfe und Gynäkologie*, March, 1901.

Use and Abuse of the Galvano-Cautery in Nasal Surgery.—C. D. Conkey lays down the following rules: 1. The objections raised against the cautery are founded upon its improper use. 2. As a matter of routine practice it should not be used upon the roof of the nose, the middle turbinate, the vault of the pharynx, the soft palate, and the uvula. 3. Upon the septum only when much hypertrophied or deeply congested, and then the burn should be neither deep nor extensive. 4. Upon the lower turbinate it may be used to great advantage, confining the applications as much as posible to thrusts, and avoiding large electrodes. 5. In the throat it may be used to the greatest advantage upon the tonsils, pharyngeal hypertrophies and follicles, and at the base of the tongue to destroy dilated blood-vessels and hypertrophied glandular tissue, but using it so as to avoid contact with the epiglottis.—*Medical Age*, March 10, 1901.

A Contribution to the Study of Intestinal Sand.—Sir Dyce Duckworth and Archibald Garrod report a case of true enteric lithiasis, in a woman of thirty-three, having a gouty predisposition with a family history of disorders of the bowels. The sand consisted of minute granules 0.05–0.2 mm. in diameter, yellow or brown, not crystalline, and of various and irregular shapes. The material was analyzed, with the following results: Water, 12.40; organic matter, 26.29; inorganic matter, 61.31. One hundred parts of inorganic residue contained: Calcium oxide, 54.98; phosphorus pentoxide, 42.35; carbon dioxide, 2.20; residue containing traces of magnesium and iron, 0.47. Urobilin was abundant, and there were traces of unaltered bile pigment. An unknown pink pigment was also extracted from the sand.—*Medical Press and Circular*, March 6, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 Fifth Avenue.

New York, April 13, 1901.

REGULATION OF MARRIAGE.

IN past ages and among some of the highly civilized and cultured peoples who ruled over a large part of the old world, two thousand and more years ago, there was a practice of killing those children soon after birth who were not esteemed sufficiently robust to fight the battle of life with credit and benefit to themselves and the community at large. This custom was especially carried into effect in Greece. In Sparta, under the Lycurgan laws, every child born was inspected, and if in the opinion of the ephors it did not attain to the required standard of physical excellence it was forthwith despatched. The result of these summary methods of maintaining the health and physique of the race was shown in the magnificent bodily and mental superiority of the Greeks to, perhaps, the inhabitants of any civilized land at that period. In primitive nations similar modes of weeding out the unfit have been and are still in vogue.

But times have changed, and with them customs, and in civilized countries it would hardly be in keeping with these enlightened days to revert to so barbarous a practice. The belief has for long existed that something should be done to prevent, or at any rate to check, the propagation of weakly and unhealthy progeny. The question is one that concerns all classes of society, and the medical profession most intimately, inasmuch as its members are depended upon to educate the general public on the matter as well as to suggest remedies. It would be superfluous to remark that the subject is beset with manifold and intricate difficulties from whatever standpoint it is regarded. Sociologists everywhere have brought forward plans to overcome the evil, most of which have been well meaning, but utopian and impossible.

Dr. Harvey Campbell, in the London *Lancet*, September 10, 1898, wrote an able article, urging that people must be taught to understand the bad effects that will accrue to the race from marriages among the diseased, and said he was of the opinion that when they had thoroughly grasped the significance of the fact they would of their own free will forbear from procreation. He is a believer in natural selection, but is conscious that it cannot do its work effectively in civilized countries; its action is constantly defeated, and many weakly individuals are saved, who, if they were forced to struggle for existence, or to rely in any way upon their physical powers, would fall inevitably by the wayside. The consequence of this is that disease is not only perpetuated but increased.

There can be no doubt that Dr. Campbell is right as to the deterioration of the race part of his argument, but even the most sanguine will be sceptical with regard to the realization of his hope that the people will voluntarily redeem themselves. A large number of persons in this country hold strongly to the view that the State should step in and forbid by law the marriage of the unfit. But before dealing with this phase of the question it will be well, perhaps, briefly to review the diseases which, from their communicable nature and from their baneful effects upon the offspring of those afflicted, should be made from this point of view the objects of prohibitive measures.

First in the list may be placed insanity, idiocy, and epilepsy. As to the marriage of congenital imbeciles, chronic epileptics, or those who have been insane, probably no rational individual will be found to object to prohibitive legislation in their case. Some go even further and contend that a person who is descended from insane stock has no right to propagate his species. The statistics regarding insanity are startling in their impressiveness, and would appear to give weight to this contention.

In the annual report of the British Commissioners in Lunacy for 1898, giving the percentage of cases of insanity in patients under cognizance of said commissioners for five years—1893-97 inclusive—hereditary influence was attributed as a cause in 20.4 per cent. of male and in 25.9 per cent. of female patients. Records from other sources show even a higher percentage.

Next tuberculosis may be considered. Tuberculosis, at a conservative estimate, kills from eight to ten per cent. of the human race, and the marriage of individuals suffering from this malady will result in the propagation of a progeny predisposed to contract the same disease.

Venereal diseases, again, are responsible for an untold amount of suffering to those infected—often innocently—and for innumerable tainted offspring. To gonorrhœa alone are due most of women's pelvic troubles, and it is owing to syphilis that abortions and still births are so common, many marriages occurring while syphilis is in a communicable stage.

These, then, are the diseases which many physicians in different parts of the country think should be prevented as far as possible by law if necesary. It is admitted on all hands that marriage is the most fruitful cause of transmitting and perpetuating the aforesaid maladies. Therefore, it is urged, do not allow such afflicted individuals to marry. Several attempts have already been made in the United States to bring about this radical reform. The most far-reaching bill of this description as yet projected is that known as the Chilton bill, which passed the Minnesota senate on March 23d, and which, it is fully expected, will become law. This measure purposes to restrict the marriage of persons afflicted with physical or mental disorders, but, while aimed at this class, will affect all those wishing to marry, as every candidate for matrimony must undergo a physical examination by a

competent medical practitioner, and receive from him a certificate of sound health before the ceremony can be performed.

The action of the Minnesota legislature is interesting as an experiment, and, in addition, is instructive, as showing the trend of public and professional sentiment on the matter. Possibly the time is not yet ripe for placing restrictions on marriage; but a beginning should be made in some way.

In any event the working of such a law as the one in question will be watched with great interest. Even if its provisions in many instances should be covertly violated, every attempt at enforcing the law would prove a valuable educational measure, and carry with it a proper deterrent influence.

LEPROSY IN THE HAWAIIAN ISLANDS.

The above is the title of an exceptionally interesting paper read by Dr. Charles Edmond Davis before the Medical Society of the County of Albany on March 14, 1900, and before the Medical Society of the State of New York on January 29, 1901, and published in the Albany *Medical Annals* for February. Dr. Davis describes in graphic language a visit of inspection to the lepers on the island of Molokai. Upon this island are two leper colonies, the first of which is at Kalawao, on the eastern side of the island, and the second and larger one on the plain to the westward. The site chosen for these settlements is admirably adapted for the purpose, being surrounded on the north, east, and west by the sea, with the base or south side situated beneath a precipice, from one thousand to three thousand feet high, thus insuring almost perfect means of isolation. The settlement was opened in 1866, and a hospital and a home for lepers were erected. Molokai is amply provided with everything that the lepers can need, containing stores, markets, dispensaries, and cottages for their use. There are seven hundred and sixteen buildings in the settlement, and the greater part of the afflicted population live in cottages. The government supplies the lepers with liberal rations, each one's monthly allowance consisting of beef, seven pounds; salmon, five pounds; fresh fish, seven pounds; pai'ai, a native food prepared from Colocasia esculenta, and often called "poi," one bundle of twenty-one pounds net ; rice, nine pounds, with one pound of sugar; bread, eight pounds, with one pound of sugar. They are all also granted a sufficient outfit of clothes every six months. The total cost of the settlement, including the maintenance of the receiving station at Kakili, is in the neighborhood of $90,000 yearly. Dr. Davis in his paper gives a vivid although pathetic account of his visit to various homes and cottages on the island, and describes some of the cases in detail; but the most instructive portion of his article to medical men is that which treats of the origin, spread, bacteriology, and treatment of the disease in the Hawaiian Islands. As elsewhere, its origin appears to be quite obscure.

The theory that it was brought to the islands by sailors in the days of whaling ships is discredited, as in Java and in other islands of the archipelago leprosy was known to exist before the sailors had the chance to disseminate it. The fact is also known that the Hawaiians had communication with the Chinese as early as 1778, and with natives of other islands as early as the thirteenth century, when leprosy was so prevalent in Europe. It would, therefore, seem when the mass of evidence has been sifted that leprosy was introduced into the Hawaiian Islands by oriental races. Whence it came or by what means it was first brought to these islands will probably be never clearly understood; but this much stands out with prominence that in the year 1864 the spread of the disease in Honolulu and other places aroused general alarm, and through the unwearying efforts of the missionaries the legislature of the kingdom of Hawaii in 1865 enacted a law to prevent its spread, and in the same year a hospital with suitable buildings was established and opened at Kalihukai, on the island of Oahu, and distant from Honolulu about three miles. This station was designed for the reception, inspection, and treatment of persons afflicted with leprosy. Mild cases, after the diagnosis had been made, were treated there, and the severe or incurable cases were to be transferred to the site recently purchased at Kalawao, on the island of Molokai.

In 1866, according to the government report, the number of lepers on the different islands was 274. From 1895 to 1897 the total number of lepers on these islands was 337, while during the same period the number sent to the leper settlement was 256. At the present time there are at Molokai 1,073 lepers. The causes of the spread of leprosy are without doubt many, to careless arm-to-arm vaccination the dissemination of the disease has been attributed by some. Since, however, non-humanized virus has been used on the island for the past fourteen years, this means of spreading the complaint has been effectually prevented. Kissing and nose-rubbing, the native form of salutation, cohabitation, and the reception of the secretion of lepers through abrasions of the skin are, says Dr. Davis, also stated to be causes of communication. These, and especially sexual intercourse, he holds to be the not unlikely means of communicating infection. The mosquito, house fly, and other insects have been charged with carrying the disease, but, although in the light of recent discoveries it would be unwise to sneer at the theory, yet until the lepra bacillus has been more closely investigated, a definite opinion would be premature. After referring to Dr. Arning's celebrated experiment on the direct inoculation of leprosy, and after discussing the several forms prevailing, Dr. Davis touches upon the curability of the disease, and states that in the Sandwich Islands it is regarded as incurable, the conclusion being that of those best qualified by investigation and experience to pass an opinion. Every drug but Jatropha gossyhiplia, suggested by Dr. E. A. Carmichael, has been used lavishly in the Hawaiian Islands, with no distinctly curative effec

With the acquirement of the Hawaiian and Philippine Islands and Cuba, the United States has taken upon herself great and new responsibilities; and she

must, as far as is possible, protect her people and prevent the introduction of diseases peculiar to those lands. In all the afore-mentioned islands leprosy is more or less prevalent, and, as well pointed out by Dr. Carmichael, in its early stages extremely difficult to detect. Therefore the most stringent restrictive measures should be put into force to prevent the departure of emigrants from any port, in countries over which we exercise sway, where leprosy is endemic. The necessity for these precautions being taken has been insisted upon many times in the MEDICAL RECORD. Papers like those of Dr. Davis do good by keeping such views before the public, and by impressing upon the minds of those in power the need of carefully guarding the inhabitants of this country against the ravages of imported diseases. There are those who think that by the most rigorous segregation leprosy may in time be stamped out. The United States would be setting a splendid example to the nations if she were to attempt this task in her latest possessions.

DEATH CERTIFICATION.

PROBABLY in the vast majority of cases in which death occurs in the sequence of disease, for the treatment of which the patient has been under the care of a physician, the latter is not present at dissolution, on the occurrence of which a certificate is generally issued without actual knowledge of death or a view of the dead body. Such a course is almost unexceptionally unattended with ill results, but it cannot be denied that it opens a loophole for deception or crime which, although of rare occurrence outside of the novels, is occasionally practised, as is shown in a recent experience detailed by an English practitioner in *The Lancet* for March 2, 1901, p. 659, which confirms the oftquoted statement of the greater strangeness of truth than of fiction.

A man, thirty-five years old, applied for treatment for relief from difficulty in micturition. Several days later the physician was summoned to the patient at his room, where he was found in a weak condition, with a temperature of 103° F. He complained of severe pain in the loins and of constant headache, stated that his feet and legs swelled when he was out of bed, and that for some time he had been passing urine frequently in small amounts. The man was visited regularly in bed for eight days. Repeated examinations of the urine disclosed constantly the presence of albumin, hyaline and granular tube casts, and on one occasion also blood. At one visit the patient was found collapsed, deadly pale, almost pulseless, and suffering from a severe rigor. He explained that a fire had occurred in an adjoining room during the night, and that he had jumped out of bed almost naked to assist in extinguishing it. He then stated that he should have to send for his brother, and he gave the letter to his landlady to mail.

On the following day the man appeared drowsy and exhibited convulsive movements in the extremities. On the next morning the physician was visited by a man bearing a general resemblance to the patient, and stating that he was the brother of the latter, who had died during the night after a convulsion. The man paid the doctor's bill and received the death certificate. The suspicions of the landlady had, however, been aroused by the fact that no assistance had been called for during the night, and also that the room which contained the body had been locked up. The physician reassured her by agreeing to observe his usual habit of inspecting the corpse, though he was not required so to do either by law or by professional custom. On his arrival at the house the brother was not in, and the room in which the body lay was entered forcibly. On the bed the outlines of a human body surrounded by a coverlet were dimly visible in the darkened chamber. On closer inspection, however, it was found that the supposed corpse was made up.

Later in the day it was learned that the patient was a senior medical student carrying a policy of life insurance for two hundred pounds. When the "brother" was confronted with the facts he confessed to being at once patient, corpse, and brother, and he explained that he had entered upon the plan for the purpose of making his relatives believe him dead, as he had just been released from prison. He admitted that he had added albumin to his urine, although ill, while his elevation of temperature was genuine. After the physician's last visit, the man had gotten out of bed, shaved off his mustache and reappeared as his own brother.

Apart from the unusual interest of this remarkable case, it is not without practical bearing in pointing out the desirability of legislation making it necessary that after death the body shall be viewed in every instance by a properly qualified person, and that not alone the cause but also the fact of death should be certified.

THE RELATION OF THE PITUITARY BODY TO ACROMEGALY.

ALTHOUGH lesions of the pituitary body have been found in the majority of cases of acromegaly in which post-mortem examination has been made, they have not been detectable in a considerable proportion of cases, while, in still another group, disease of the pituitary body has been unattended with symptoms of acromegaly. It must, therefore, be considered an open question whether the clinical manifestations are the result of the anatomical lesion, or whether both may not be due to a common cause. Some experimental observations made by Friedmann and Mass (*Berliner klin. Wochenschrift*, 1900, No. 52, p. 1213) go to show that the pituitary body can be removed by operation through the mouth, without necessarily causing death or being followed by the development of symptoms of acromegaly or of changes in the thyroid gland. The success of the operative procedure suggests the possibility of its application in human surgery, not alone for the removal of tumors of the pituitary body, but also for the purpose of providing a channel for the escape of effusions, as in the various forms of meningitis.

THERE is at present an unusal prevalence of a malignant type of scarlet fever in New York and vicinity.

News of the Week.

American Gastro-Enterological Association. — The fourth annual meeting will be held in the banquet hall of the "Shoreham," Washington, D. C., Wednesday, May 1, 1901.

Dr. Frederick A. Packard has been elected a trustee of the University of Pennsylvania, in succession to the late Dr. J. M. Da Costa. He is a graduate of the department of arts of the University of the year 1882, and of the medical department of 1885, and is physician to the Pennsylvania Hospital and the Children's Hospital.

Prof. A. Jacobi's Reception.—Our distinguished townsman celebrated the completion of his fiftieth year as a physician by entertaining his many friends at the Academy of Medicine on the evening of April 5th. He was graduated at the University of Bonn, April 4, 1851. The celebration of his seventieth birthday by a notable dinner last year is still fresh in the minds of his professional brethren. As an evidence that he has lost none of his youthful enthusiasm he read an elaborate and highly finished paper on "German Text-books of Half a Century Ago."

National Association for the Study of Epilepsy. —The first annual meeting of the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics will be held in Washington, D. C., May 14th and 15th next. Many papers of value from European and American students, and full reports of the progress that is being made in the care and treatment of epileptics in this country, are promised for this meeting. The president of the Association is Hon. William P. Letchworth, LL.D., Portage, N. Y.; first vice-president, Frederick Peterson, M.D., New York City; secretary, William P. Spratling, M.D., Craig Colony, Sonyea, N. Y.; any one of whom, upon request, will give further information of the coming meeting.

Heroism of a Royal Army Medical Corps Officer. —The president and council of the Irish Medical Schools and Graduates Association entertained, on Saturday, March 16th, a distinguished company at dinner at the London Hotel; Cecil, Lord Roberts being in the chair. The occasion was the presentation to Captain Charles Dalton, R.A.M.C., of the Arnott Memorial Medal for his bravery at Chieveley, South Africa, on January 23, 1900. Mr. David Arnott is the donor of the medal, which he presented in memory of his late father, Sir John Arnott. It has fallen to the lot of Captain Dalton to be the first to win this distinction. The 14th Hussars, to which regiment the doctor was attached, were taking part in a reconnaissance near Chieveley, and it became known that an officer of the South African Light Horse was lying wounded within the zone of fire. Captain Dalton forthwith obtained permission to go and dress his wounds. This he was proceeding to accomplish when the Boers fired a volley at them, at one hundred yards range, paying no attention to the Red Cross flag carried by the doctor's orderly. The result was that the orderly was shot dead and the doctor received a bullet wound in the abdomen.—*The London Sketch.*

Pure-Beer Bill for Great Britain.—This bill was read for the second time in the English House of Commons on Wednesday, March 27th. The *London Daily Telegraph* points out that, under the scheme in its present form, beer is divided into two classes—malt beer and part-malt beer. Malt beer is described as the product of barley malt, with the addition of hops, yeast, water, and such substances for the preparation of beer as may be approved by the commissioners of inland revenue. Part-malt beer means any beer other than malt beer. While brewers who employ malt substitutes will be allowed to call the product beer, they will be obliged to sell it under a designation which indicates that other ingredients have entered into its composition, and thus the main purpose of the champions of pure beer will be accomplished.

The Loomis Sanatorium Charitable Annex.—The Loomis Sanatorium, Sullivan County, N. Y., has recently had built an addition in the form of a charitable annex. The patients in this part of the institution are charged five dollars a week and receive—over and above their board, lodging, medical attendance, medicines, and laundry—the same treatment in the way of scientific cure and supervision as in the main sanatorium. The deficit between the five dollars a week charged to the patients and the actual cost of maintenance is made up by a maintenance fund raised annually by a subscription. Dr. J. Edward Stubbert, physician in charge at the main sanatorium, visits the annex once a week as consulting physician, while two of its resident house physicians constitute the regular visiting staff, making daily visits and keeping daily office hours at the annex. The nurses are furnished from the training-school at the main sanatorium. The annex has a capacity for twenty-four patients, and at present contains twelve. It is hoped that funds may be raised to enlarge the institution, so that many more patients may be cared for. The various medical examiners for the main sanatorium will also examine applicants for admission to the annex, but the rules for receiving only incipient cases are even more rigidly enforced in the case of the latter establishment than in that of the former.

American Academy of Medicine.—The twenty-sixth annual meeting of the American Academy of Medicine will be held at the Hotel Aberdeen, St. Paul, Minn., on Saturday, June 1, 1901, at 11 A.M. (executive session; the open session beginning at 12 M.), and continuing through Monday, June 3d. The principal features of the meeting will be a symposium on "Institutionalism," and another on "Reciprocity in Medical Licensure." Series of valuable papers on both topics have been promised, as well as interesting papers on some other subjects. The president's address (S. D. Risley, M.D., of Philadelphia) will be delivered on Saturday evening, June 1st, and the annual social session will be held on Monday evening, June 3d. Members of the profession are always wel-

comed to the open sessions of the Academy. The secretary (Charles McIntire, M.D., Easton, Pa.) will be pleased to send the programme, when issued, blank applications for fellowship, etc., when requested to do so.

New York Academy of Medicine.—At the next meeting, April 19th, there will be a symposium on "Dull and Mentally Deficient Children," conducted by the section on pediatrics. A goodly number of speakers will present different phases of the subject, and the occasion promises to be a most interesting one.

Christian Science in Berlin.—The *Deutsche Evangelische Kirchen-Zeitung*, the leading Protestant organ in Germany, bitterly complains that of late "the so-called 'Christian Science' has been imported from America, and is now being spread by Americans residing in Germany, particularly in Berlin." The paper declares that the movement is making rapid progress among the higher, and even the highest, classes, although exclusively among women so far.—*New York Times.*

Cutaneous Manifestations in Diabetes.—Dr. S. Sherwell, of Brooklyn, writes: "I would respectfully ask (a thing not often necessary) for a correction of a report in your journal of April 6, 1901, p. 557, of my remarks in connection with the consideration of cutaneous manifestations in diabetes. I did not use the expression 'generalized scleroderma,' but 'generalized xeroderma,' a somewhat different thing. As also I referred to the appearances within the mouth and upper air passages 'of the gummy *mucus*' (not mucous membrane), reminding one of the 'ribbed sea sand, or ooze,' left by a retreating tide—thus, as will be seen, infusing a tender poetic touch into an already sweet theme."

Anti-Spitting Crusade.—The crusade against promiscuous expectoration in public places and street cars is proceeding with great spirit, and, it may be presumed, with a fair measure of success. A number of persons who indulge in this filthy habit, careless of the health of others and of the ordinary decencies of life, have been arrested, and the majority of them fined. This energetic action on the part of the president of the board of health must be highly commended, as the notices of the board were more "honored in the breach than in the observance"—were practically, in fact, regarded as a dead letter. The fining of offenders should be a salutary warning to others who may be accustomed to spit wherever they feel inclined.

Public Schools' New Roof Gardens.—It is proposed to remodel the roofs of many of the public schools, in order to facilitate an experiment which is to be tried this summer in connection with the vacation schools. It is intended to teach the pupils of the public schools gardening. Looking around for a suitable place for practical study, the attention of the superintendents was drawn to the roofs of the different school buildings. The greatest difficulty to be overcome in such a garden would be the high winds and their consequent menace to the safety of the plants. This danger is to be guarded against by arranging wind breaks, in the shape of high walls. To make the school roof garden practical, as many of the plants if set out at the usual time would hardly be started before the summer vacation began, forcing-frames will be built. In them seeds may be planted even in midwinter. These frames under glass are to be arranged around the sides of the roof and protected from the winds by the high walls of the building. This will enable the children to raise plants on the roof from early March until midsummer. A row of boxes filled with soil will be added, in which new seeds can be sown, or to which the growths in the forcing-frames can be transplanted. A real true garden, as the children say, can thus be established. Not only annuals, but perennials, will be grown.—*New York Herald.*

Medical Decorations.—A supplement to the *London Gazette*, March 19th, announces that King Edward has appointed Sir William Henry Broadbent, M.D., to be Knight Commander of the Royal Victorian Order and A. R. Manley, M.D., to be a member of the fourth class of the same order. Dr. Manley is a country practitioner in Norfolk, the county in which Sandringham, the former country seat of the king, when Prince of Wales, is situated. Dr. Manley had been for many years surgeon apothecary to the Prince of Wales, and had attended him and his family when in Norfolk. Dr. Manley has been given the same position with the king.

Home for Inebriates.—Senator Trainor introduced, on April 5th, a bill to incorporate the Inebriates Home for New York City. By the provisions of the bill, the city of New York is authorized to pay the home a sum not exceeding five per cent. of the annual revenues of the liquor-tax law, for the care and support of habitual drunkards committed to the home by any magistrate, and for the founding, equipping, and maintaining of the home; or the city authorities may contract with the home to care for destitute drunkards and pay for their care out of the excise revenues. The home may take private patients at private rates, and the expense of their care and support is not to be charged to the city fund assessment.

Dr. Vaughn on Women Medical Students.—Dean Victor Vaughn, of the University of Michigan, has given vent to an expression of opinion with respect to female students of medicine which will doubtless raise the ire of those who hold that women are as well fitted to engage in the liberal professions as are men. Of course Dr. Vaughn restricts his remarks to embryo lady doctors. Speaking before his class in hygiene and taking as his text "Women's lack of originality," Dr. Vaughn said: "Once a year I like to tell my opinion of women engaged in the study of medicine. In text-book work generally a woman student will make a better recitation than a man, but when it comes to relying on personal judgment she nearly always fails in efficiency. There are brilliant exceptions to the rule, but when a young woman is thrown on her own resources in a laboratory she fails to come up to the standard set by the students of the opposite

sex"; which means that a woman, although industrious and able to retain facts learned from books as well as a man, is lacking in self-reliance, and is, therefore, placed at a disadvantage when it comes to research or practical work.

Two Women Doctors in South Carolina.—Two young women have just been graduated from the Medical College of South Carolina. They are the first women graduates of the institution and also of the State.

Smallpox and the Glasgow Exhibition.—In view of the exhibition, says *The Hospital*, so shortly to be opened in Glasgow, strenuous efforts are being made to arrest the smallpox epidemic, more especially by vaccination. A large number of students are being employed to go from house to house in the poorer districts to vaccinate the inhabitants. Primary vaccination can be effected only by registered medical men, and a large number of these are also being invited to join the crusade.

Dr. W. W. Keen.—A portrait of Dr. Keen, professor of the principles and practice of surgery in Jefferson Medical College, has just been presented by the students of Jefferson Medical College to the college, the presentation address being made by Dr. J. Chalmers Da Costa, and the speech of acceptance by Mr. William Patten, president of the board of trustees. Dr. Keen has been granted a year's leave of absence, and contemplates a tour of the world.

College of Physicians of Philadelphia.—At a stated meeting held April 3d, Dr. James Tyson read a "Memoir of the Late Dr. William Pepper." Dr. S. Ormond Goldan, of New York, read by invitation a paper entitled "Nitrous Oxide and Oxygen as a Surgical Anæsthetic; Description of a New Apparatus for Administering these Gases; Report of One Hundred Operations, the Narcosis Lasting Half an Hour and upward; Remarks Regarding the Use of Nitrous Oxide as a Preliminary to Ether in General Anæsthesia." Dr. Goldan made a plea for the careful training of hospital physicians in the administration of anæsthetics, and also for the selection of that anæsthetic agent best adapted to meet the indications in the individual case. He showed that the combination of nitrous oxide and oxygen may be employed with safety and with the avoidance of many of the dangerous and disagreeable effects of other anæsthetics. While the cost is considerable, this fact would not weigh in the matter of saving life. The discussion was participated in by Dr. John D. Thomas, Dr. Thomas R. Brown, of Baltimore, who spoke especially of the use of nitrous oxide and ether, and Dr. John G. Clark.

Precautions against Rinderpest.—Rinderpest has been reported to exist in the Philippine Islands. Secretary Wilson has accordingly recommended to the secretary of war that every precaution should be taken to prevent its introduction into the Hawaiian Islands and the United States by the agency of animals conveyed on government transports. He further requested the secretary of the treasury that special measures be enforced on the Pacific coast, to prevent the landing of susceptible animals without their being turned over to the Department of Agriculture for quarantine, under the supervision of the Bureau of Animal Industry. Rinderpest is the most deadly disease to which cattle are prone. It is contagious in a high degree, and in times gone by has frequently swept through Europe, destroying nearly all the members of the bovine tribe. In Africa during the past two or three years the disease has been very conspicuous by its ravages. In many districts of that continent it killed from ninety to ninety-five per cent. of all cattle. Inoculation has somewhat restricted the scope of its devastations, but it still remains a serious, if not the most fatal, disease to cattle.

To Create a Board of Parole.—Senator Wilcox's bill, providing for the creation of a board of parole, to parole prisoners confined in the State prisons and the Eastern Reformatory at Elmira, was passed.

Bill for a Superintendent of Forests.—The assembly passed the senate committee bill, providing for the appointment of a superintendent of forests, who is to have general supervision of the forest preserve and forestry interests of the State.

Physicians for the Newfoundland Sealing-Fleet.—For the first time in the history of the Newfoundland sealing-fleet, says the Canadian correspondent of *The Lancet*, physicians accompanied it. The fleet numbers about six thousand sailors, and left St. John on March 9th.

Philadelphia Academy of Surgery.—At a stated meeting held April 1st, Dr. John A. Wyeth, of New York, read a paper entitled "Amputation at the Hip Joint for Sarcoma; the Tendency to Recurrence." The discussion was participated in by Dr. W. B. Coley, of New York; Dr. J. C. Bloodgood, of Baltimore; and Drs. W. W. Keen, John B. Deaver, and Simon Flexner, of Philadelphia. The meeting was followed by a reception at the Hotel Bellevue.

Compulsory Vaccination Sustained by the Supreme Court of Pennsylvania.—The city of Philadelphia and the State of Pennsylvania are to be congratulated upon a decision rendered by the supreme court of that State, sustaining the ruling of a lower court, to the effect that an act making the vaccination of children a prerequisite to admission to the public schools is constitutional and valid. The wisdom of the court is exibited not less in its decision than in the grounds therefor. "We think," the opinion says, "that the court below did not err in the ruling referred to in the assignments. In Duffield *vs.* Williamsport School District we held that school directors, in the exercise of a sound discretion, may exclude from the public schools, pupils who have not been vaccinated. Whether a resolution excluding from the school, pupils who have not been vaccinated, is a reasonable one is to be judged of in the first instance by the school directors. In the present state of medical knowledge and of convincing opinion of those having charge of the public health, the courts

will not say that such a resolution is an abuse of official discretion." The decision was the outcome of a mandamus suit brought in the city of Philadelphia by the father of a child that was denied admission to a public school on account of not being vaccinated in accordance with a rule of the board of education and an act of assembly. The demurrer of the plaintiff was overruled by the court of common pleas, and this decision has now been sustained by the supreme court.

Smallpox in Ontario.—The situation as regards smallpox in this Canadian province is stated to be serious. Ontario is on the verge of a smallpox epidemic. The disease is widely disseminated, being located in fifteen centres, and something like one hundred cases have been reported, with two deaths.

Navy Department, Bureau of Medicine and Surgery, Washington D. C.—Changes in the medical corps of the navy for the week ended April 6, 1901. Dr. A. E. Peck appointed assistant surgeon from March 24, 1901. Medical Director W. K. Scofield placed on the retired list, April 28, 1901. Surgeon G. Pickrell granted sick leave for three months from April 2d. Assistant Surgeon E. M. Blackwell detached from the *Abarenda*, upon reporting of relief, and ordered home to wait orders. Assistant Surgeon R. C. Marcour detached from Havana naval station and ordered to the *Abarenda* after temporary duty on the *Philadelphia*, May 4th. Assistant Surgeon E. Davis granted sick leave for three months. Medical Director G. F. Winslow detached from Boston navy yard, April 18th, and ordered home to wait orders. Medical Director E. Bogert, retired, ordered to the Boston navy yard, April 18th. Passed Assistant Surgeon E. R. Stitt, commissioned surgeon from June 7, 1900. Pharmacist J. Cowan detached from the *Glacier* and ordered to the *Manila* and to additional duty at the naval hospital, Cavite. Surgeon C. F. Stokes detached from the *New Orleans* and ordered to the *Solace* upon her arrival on the Asiatic station.

Timber Preservation.—The *New York Tribune*, Sunday, March 31st, says: "The forestry division of the agricultural department is engaged in drafting a working-plan looking to the conservation of the timber on a tract of three hundred thousand acres in the neighborhood of Millinocket, Me., belonging to a private paper corporation. It is part of a general policy to be inaugurated by the department for the conservation of timber land throughout the United States to secure a perpetual crop of timber in the areas under consideration. The private concern will pay all the expense of the work, except the salaries of the government experts, who are directed by Professor Gifford Pinchot, chief of the division."

Amending Christian Science Bill.—Assemblyman Bell, in view of the opposition to the above bill in its present form, has proposed to amend it in order to remove all opposition. This action on the part of Mr. Bell has, according to the *New York Tribune*, Sunday, March 31st, displeased the members of the Medical Society of the County of New York. Mr. Bell sent word that he would like to hold a conference on the subject with Drs. Frank Van Fleet and Robert T. Morris and a delegation of Christian scientists. Dr. Van Fleet said it looked as though a mistake had been made in allowing Mr. Bell to present the society's bill. He added that the bill would go through in the form in which it was originally drafted or Mr. Bell would be responsible for the alterations.

American Losses in the Philippines.—The losses of our troops in the Philippines since August 6, 1898, are as follows: Killed, 741; died of wounds and accident, 472; died of disease, 2,295; total deaths, 3,508; wounded, 2,638; grand total, 6,146.

Death of a Well-Known Australian Physician.—Dr. Leo E. F. Neill died suddenly of pneumonia at Sydney recently. The deceased had a brilliant career at Sydney University, where he was graduated with honors in medicine in 1890. He was then resident physician at the Prince Alfred Hospital for two years; after which he visited America, and made himself familiar with the methods obtaining in the leading hospitals there. On his return to Australia he settled in Sydney, and quickly made his mark.

Death of an Eminent Foreign Medical Man.—Dr. Manassein, of St. Petersburg, one of the most distinguished physicians in Russia, died quite recently. He was born in Kazan in 1841, and after studying medicine in Moscow and Dorpat travelled abroad to various foreign universities. At Tübingen he worked under Professor Hoppe-Seyler, and was entrusted by him with the charge of the "castle laboratory." On his return to Russia Dr. Manassein became assistant to Professor Balkin, and in 1876 was appointed clinical professor. His chief work lay in experimental pathology. For many years he was editor of the chief Russian weekly, the *Vrach*.

Obituary Notes.—Dr. R. Erskine Johnson, one of the resident physicians in the State Hospital for the Insane at Danville, Pa., died on April 3d, at the age of thirty-five years, after having been struck several times by a patient whose temperature he was in the act of taking. Post-mortem examination showed that death had resulted from a wound of the aorta made with a knife blade.

Dr. Charles Roy King died at Torresdale, Philadelphia, on April 5th, at the age of eighty-eight years.

Dr. William Stites died on February 22d at his home, Washington, N. J., aged sixty-eight years. He was graduated from the University of Pennsylvania in 1868. He was the prime mover in organizing the Washington board of health, and for many years was its president. He was also division surgeon of the Lackawanna Railroad up to last December, when he resigned. He was a member of the Warren County Medical Society, the Lehigh Valley Medical Association, and the Tri-County Medical Association, having been president of the first-named organization in 1892. He was also quite prominent in Masonic circles, having been a member of Temple Chapter No. 12,

R. A. M., and a Past Master of Mansfield Lodge No. 36, F. and A. M., and was a devoted and helpful member of the Methodist Episcopal church of Washington.

Dr. William Taliaferro Hord, medical director of the United States navy, retired, died at his home in Washington on April 1st after a seven weeks' illness. Dr. Hord belonged to a distinguished Virginia family. He was born in Maysville, Ky., on March 3, 1832, his father being Judge Francis Triplett Hord. Dr. Hord was educated at the University of Pennsylvania, and was appointed an assistant surgeon in the navy in 1854. He served with distinction during the war, being with Gen. William Nelson from Pittsburg Landing to Corinth, and in the South Atlantic blockading squadron, and in the operations about Charleston. A widow and two sons survive him.

Dr. Alfred Spearman, of Milwaukee, died at Philadelphia April 1st, as the result of a surgical operation, at the age of sixty-nine years. He was born at Smyrna, Del., and was graduated from Jefferson Medical College in 1852.

Dr. John H. Grove died at Philadelphia, on April 6th, at the age of seventy-six years. He was graduated from the medical department of the University of Pennslyvania in 1849, and at the outbreak of the Civil War became a brigade surgeon in the United States volunteers, with the rank of major. He later became lieutenant-colonel, and he served until 1865. He was medical director of St. Agnes' and St. Mary's hospital and a member of numerous organizations.

Progress of Medical Science.

New York Medical Journal, April 6, 1901.

The Comparative Pathology of the Jews.—Concluding article by M. Fischberg. The ideas advanced are summarized in the following propositions: (1) The death rates of the Jews, at all ages, are relatively and absolutely lower than those of the people among whom they live. (2) The marriage rates and birth rates of the Jews are smaller than those of the Christians; the Jews increase in number more rapidly than non-Jews because they lose by death relatively fewer children and bring more to maturity. (3) The Jews die less often than their neighbors from many of the infectious disease, particularly epidemic cholera, smallpox, and tuberculosis. (4) Syphilis and alcoholism, and also diseases due in great measure to their poisons, are comparatively rare among the Jews. (5) Diabetes is very frequent among the Jews. Most observers have recorded that almost twenty-five per cent. of all the cases of diabetes occur in Jews. (6) All the functional neuroses and psychoses, particularly neurasthenia and hysteria, occur more frequently among Jews than among non-Jews; while all the organic nervous diseases, as tabes, general paralysis, etc., are less frequent, commensurate with the infrequency of syphilis and alcoholism among them. The great majority of cases of amaurotic idiocy occur in Jewish children, and insanity is met with among Jews between two and five times more often than among Christians. (7) Blindness, color-blindness, trachoma, and glaucoma, and also varicose veins, particularly hemorrhoids and hernias, are very frequent among Jews. (8) All these peculiarities in the comparative pathology of the Jews are not due to any ethnic, "biostatic," or racial characteristics of a purely anatomical or physiological nature in relation to non-Jews. They have their origin in the past history of the Jews, in their habits of life, and in the fact that syphilis and alcoholism have but rarely been seen among them. (9) Where the Jew is commingling with his Christian neighbors and adopts their customs and habits of life, he sooner or later loses his "racial characteristics," and his comparative pathology presents no special peculiarities.

The Active Principles of Digitalis Leaves.—By J. W. England. The author discusses the various and conflicting statements made by different authorities on the subject of the principles of digitalis leaves and concludes by saying that the chemistry of the latter cannot be regarded as being satisfactorily settled. If the claim that the glucosides of the leaves are different chemically from those of the seed is a fact—and it seems singular that such a difference should exist between the glucosidal principles of the leaves aud of the seed of the same plant—it means that equally as great differences in the physiological activities of the principles may exist, and these differences, if existent, would serve to explain much of the seeming confusion that has heretofore obtained in the reports made by different investigators upon the chemical nature and the physiological properties of digitalis principles. New investigations are needed upon the glucosides prepared from the leaves (not from commercial products obtained from the seeds); and these investigations should be made along new lines, leaving unconsidered all the work that has been heretofore done upon digitalis principles.

Rectal Feeding in Throat Diseases.—A. C. Bardes claims that many cases of throat disease require artificial feeding in order to remove every possible cause of irritation from the diseased structures. He includes among the conditions to be so treated, diphtheria, tuberculosis, and hay fever with asthma. The advantages of the method are: (1) The throat, being at rest, is not irritated. (2) Struggling in children is obviated. (3) The progress of the disease is shortened. (4) There is no danger of food entering the larynx. (5) The physician is able to give such food and stimulation as he wishes to give. (6) The food is not bolted, as it is when swallowing is painful.

The Pathology of Intra-Uterine Death.—By Neil McPhatter.

The Medical Aspect of Christian Science.—By W. M. Polk.

Medical News, April 6, 1901.

The Question of Drainage in Appendicitis.—A. M. Pond, in discussing this subject, states that the peritoneum is capable of disposing of large quantities of pus under favorable conditions, chief of which is equal distribution over the peritoneal area. In order to accomplish this, some agent must be used which is capable of dissolving pus and pus-forming elements. In relation to the choice of this agent, several points are important: sterility, because a species of bacteria, which by itself is often inert or latent, becomes, when combined with another, the source of a rapid infection; power of holding in homogeneous solution the blood and blood clots incident to the operation as well as the pus, in order to allow equal distribution over the peritoneum; stimulation of absorption, so that all septic material may be removed as soon as possible. Hot saline solution is very effective and fulfils all the requirements. Increased hepatic activity is another step in the right direction. Posture is of great advantage in these cases: elevation of the foot of the bed gravitates the fluids toward the diaphragm where absorption is increased by means of the diaphragmatic lymph spaces. The author reports six cases in which after the operation the peritoneal cavity was flushed with hot sterile salt solution, while a gloved hand searched the abdomen for more abscesses. The fluid was then gently pressed out, the cavity wiped with sterile gauze, then filled again with the hot saline solution, and the wound closed. When the technique was unquestioned, the results were most satisfactory. The author believes the old maxim is about to be revised to "when in doubt, do not drain."

New Methods in Charity, with Better Results and at Less Cost.—William P. Spratling recommends the following: (1) Prevent insanity, epilepsy, imbecility, idiocy, and feeble-miudedness as far as possible by making it impossible for persons so afflicted to marry. (2) Build less expensive structures in which defective and dependent State charges shall live. (3) Maintain at less cost the cases that are chronic and incurable, and maintain at greater cost, to stimulate recovery, those that probably can be cured. (4) Give those that ought to have it an education that they can use, either in the institution that cares for them, that the cost of their maintenance may be lessened, or in the outer world, when they leave the institution, after the State has done its work well and turned them back into the great business current, as nearly normal men and women as science and art can recreate them.

Resection of the Cervical Sympathetic.—By Howard J. Williams.

Advertising in the Profession.—By Frauk Lydston.

The Boston Medical and Surgical Journ., April 4, 1901.

Diseases of the Myocardium.—Heury Jackson says, among other things, that the existence of a murmur does not necessarily imply the presence of an organic valvular lesion. It may be a functional murmur, or it may indicate a disease of the myocardium. The author classifies these

diseases as follows: (1) disturbance of the circulation; (2) inflammatory processes; (3) degeneration; (4) various new formations—tumors; (5) hypertrophy and dilatation. He speaks in detail of the changes which give rise to symptoms producing the clinical picture of "heart disease."

The Condition of the Myocardium as Affecting Cardiac Murmurs.—H. D. Arnold says that whenever a murmur exists it is of great importance to investigate the condition of the myocardium. By so doing we may find the cause of the murmur in an entirely remediable condition of the cardiac muscle, and we may save ourselves the mortification of ascribing it to incurable valvular disease, and we may spare our patient the life of worry and dread which the latter diagnosis so often causes.

A Further Note on the Treatment of Epidermoid Cancer.—Francis H. Williams reports a case in which an epidermoid cancer of the lip was healed by exposure to the radiation from an excited Crookes tube. Photographs of the patient before and after treatment illustrate the article.

A Case of Ununited Fracture of the Femur in a Child in which the Non-Union was Due to the Formation of a Cyst at the Ends of the Fragments.—By J. E. Goldthwait.

Paraplegia Existing from Birth; Laminectomy at the Age of Five and One-Half Months.—By R. W. Lovett.

Multiple Plexiform Fibromata.—By H. L. Burrell.

The Jour. of the Amer. Medical Ass'n, April 6, 1901.

Some Observations in Renal Surgery.—W. H. Allport reviews fourteen cases and summarizes the errors with which they appear to have been fraught, drawing the following lessons therefrom: The surgeon should not attach too great weight to the recollections or the subjective symptoms of the patient, unless they are borne out by the physical signs. Nevertheless, due weight should be given to statements made by intelligent patients, especially in cases in which the objective testimony is abundant but confusingly contradictory. No diagnosis of tumor or structure is complete until consideration has been given to the possibility of the encroachment by organs or growths on the normal sites of organs which *prima-facie* evidence would lead us to believe to be the ones involved. Every diagnostic resource should be followed up faithfully to its logical conclusion. In operation, the ureter should be properly cared for. Kidney stumps should not be ligated with silk. Too deep incisions into the kidney structures are dangerous. The kidney and the operation wound should not be closed primarily after nephrotomies. Drainage for a few days, at least, is much safer. A kidney riddled with sinuses is best removed. It is an error to base an incision on any preconceived idea of diagnosis.

The Relation of Indicanuria and Oxaluria to Gastro-Intestinal Fermentation.—J. A. Wesener states that traces of oxalates are found normally in the urine, having been taken in with the food. Oxalate crystals usually denote gastro-intestinal fermentation. Food rich in oxalates must be excluded. Abundance of oxalate crystals does not signify high acid percentage, because, in addition, there may be oxalate of lime in solution. Indican is often, but not necessarily, associated with oxalate crystals. Hyperacidity on a meat diet contributes to putrefaction, whether due to excess of hydrochloric acid or acids of fermentation. In certain disturbances of the gastro-intestinal tract due to excess of hydrochloric acid or to excess of fatty acids, in which there is fermentation, indican and oxalic acid are increased. The symptoms of oxalic-acid diathesis associated with indicanuria are not due to the oxalic acid nor to the indol, but to other products formed in the process of fermentation, and therefore the oxaluria and indicanuria are valuable as indicative of a putrefaction, to which the symptoms are to be referred. The study of oxaluria and indicanuria holds open a rich field for investigation.

A New Leg Splint for Transverse Fracture of the Tibia.—Edward A. Tracy, in describing this splint, states that after the fracture is reduced, a piece of wood-plastic material is suitably cut, moistened with water, and bandaged snugly upon the limb directly next the skin, so that it embraces the shin bone. The middle line of the long axis of the splint coincides with the anterior border of the tibia. This splint, lying next the skin, gives an efficient immobilization. It is light, cheap, and durable. At any time the surgeon can inspect the bone by unwinding the bandage and lifting up the splint. It permits of massage, which is very important. There are no bits of wood nor tin strips to be kept in place, no cotton batting to impair fixation, no flannel bandage, and no mussy application of plaster-of-Paris. Should the apparatus need to be loosened in the absence of the surgeon, it can be done by unwinding the bandage.

Chloralose.—James Tyson concludes that chloralose is a prompt and safe hypnotic, more prompt in its action than any drug except morphine. From a large experience with chloralose, the author believes that it is more prompt in its action than chloral and efficient in much smaller doses than the latter drug. Its effects occasionally include involuntary actions, which, while surprising and even fantastic in some of their exhibitions, are, nevertheless, harmless. The drug needs to be further studied. The maximum dose is gr. v. in a capsule, which may have to be repeated in not less than an hour; it should be tried also in smaller doses, because it is reasonable to believe that the unfavorable effects may be thus averted while the hypnotic action may be continued.

Individual Prophylaxis.—W. A. Evans, in regard to bacterial disease, speaks of four factors which tend to aid it. (1) Mental depression. This is an important factor in the beginning of infection. (2) Overexertion with its effects is most commonly observed, causing a condition of nonresistance. (3) Cleanliness: dirt is one of the elements of bad hygiene. The author calls attention to the interesting fact that wounds on the hands of farmers and machinists, in whom cleanliness is not possible, seldom suppurate. (4) Exposure to cold, to heat, to wet, etc., can determine infection in both man and the lower animals. The author believes that the individual can become hardened so that these factors will cease to predispose to infection.

Statement Made before the Committee on Public Health of the New York Assembly, at the Public Hearing on Assembly Bill 759, Regulating and Legalizing the Practice of Osteopathy in the State of New York, and Fixing Penalties for the Violation Thereof.—By Jacob Bolin.

Syphilis as a Non-Venereal Disease, with a Plea for the Legal Control of Syphilis.—By L. Duncan Bulkley.

Some Additional Observations on the Effects of Injury to Peripheral Nerves.—By D. S. Fairchild.

Recent Clinical Observations on Tinea Versicolor.—By Charles Warrenne Allen.

Post-Operative Nervous Phenomena or Artificial Menopause.—By Joseph Price.

An Operation for Cystocele.—By George H. Noble.

Philadelphia Medical Journal, April 6, 1901.

Suprarenal Capsule; its Use in Rhinological Operations.—Charles C. Royce believes that this drug prevents secondary hemorrhage and reduces the amount of primary hemorrhage to as small an amount as possible in all operative interference within the nose. In performing a turbinectomy, the naris is packed with a cotton tampon soaked in a five-per-cent. solution of cocaine. This is retained in the naris about ten minutes when it is renewed. But the second cocaine-soaked tampon is rolled in and covered with dry suprarenal capsule. The second tampon is replaced by a third, soaked only in the five-per-cent. cocaine solution. Thus complete and protracted anæsthesia is obtained. In the treatment of hay fever the author has observed much benefit from the insufflation of the dry powder but not from the internal use. He gives the following formula:

℞ Cocaine (pulv.) ..... gr. ij.
Suprarenal capsule ..... ʒ iij.
Starch ..... enough to make ʒ i.
M. S. Insufflate ad lib.

In conjunction with this he used the following with the happiest results:

℞ Heroin ..... gr. i.
Atropinæ sulph ..... gr. 1/75
Caffeinæ cit ..... gr. xv.
Sodii salicylatis ..... gr. lxxv.
M. ft. cap. No. xv. Take one three times a day.

A Preliminary Communication of a Study of the Brains of Two Distinguished Physicians, Father and Son.—Edward Anthony Spitzka, in describing these brains, thinks that perhaps the most significant feature common to both is the exposure of the insula. Heretofore it has been only in the brains of deaf-mutes, of negroes, of idiots, and of the defective classes generally in whom the opercula are commonly atrophied, that the insula has been found visible. Thus it was regarded as an indication of inferior development. The brains of the Seguins, however, present the very reverse type. Neither are the opercular regions at all defective, though they fail to come into typical apposition. The explanation is that the left preinsula is far better developed than its fellow on the right side. But in the Seguin brains this redundancy of development upon the left side is so pronounced that the insula in a quasi-struggle to reach the general cerebral surface has virtually thrust apart the opercula and made itself visible. Thus, in the highly intellectual, the causes potential in insular exposure are the excessive growth and development of the left preinsula, causing the opercula to become thrust apart. The defective exposure of the preinsula is due

to deficient development of the operenla and to the failure of these to approach each other.

The Genesis of Carcinoma of the Fallopian Tube in Hyperplastic Salpingitis, with Report of a Case and a Table of Twenty-One Reported Cases.—E. R. Le Count reports a most interesting case of this nature, in which the os abdominale was evidently open, since there was not formed the usual sac, and invasion of the peritoneal surface and adjacent tissues probably took place through this opening, by continuity of surface. About nine or ten weeks after the first operation in which the much enlarged and thickened left tube was removed, ascites reappeared and on vaginal examination a tumor the size of an orange was found on the left side. A second operation was performed and the entire peritoneum was found studded with papillomatous growths varying in size, some as large as a hen's egg. The similarity in method of growth and general histological structure to proliferating cystadenomata of the ovary is continued in the comparative benignancy of the peritoneal metastases.

An Experimental Study Concerning the Relation which the Prostate Gland Bears to the Fecundative Power of the Spermatic Fluid.—George Walker draws the following conclusions from his experiments: A removal of the anterior lobes of the prostate gland in rats has no effect on breeding; but in a certain number it diminishes the fecundating power; and in a few this is destroyed entirely. Complete excision has a very marked effect on fecundity, reducing it to almost nil when the gland is entirely removed. Partial or complete removal of the prostate has no effect upon the sexual desire and capacity. Complete removal of the gland in the adult animal has no effect on the histological structure of the testicles. Complete removal of the prostate in the young animal has no effect upon the subsequent development of the testes.

Further Observations on Epinephrin.—By John J. Abel.

The Lancet, March 30, 1901.

Note on the Treatment of Collapse of the Ala Nasi.—By W. J. Walsham. Normally, the lower lateral cartilage is doubled on itself U-like, the inner part being in contact with the lower part of the septum, while the external forms a part of the outer wall of the vestibule. The natural stiffness of the cartilage ordinarily keeps the naris open. Frequently the cartilage is collapsed so that the naris becomes almost closed. The author has tried the various dilators used for the purpose, but none of them has proved satisfactory. One of his patients resorted to the unique plan of rolling up a piece of moist cotton-wool into a ball of the size of a small pea which he poked up the vestibule into the little pit just within the limen at the angle of bending of the lower lateral cartilage. This tiny ball of cotton-wool was just sufficient to prevent the ala from collapsing, and it gave the author the clue to the method of curing the condition. It struck him that if, in place of the cotton-wool ball, he could transplant there a ball of the patient's own tissue, he would obtain the same end, and this he succeeded in doing in the following way: A strip of mucous membrane as thick as possible and about three-sixteenths of an inch in width was dissected up from the inner wall of the vestibule, leaving the base attached above. The surface of the little pit at the angle of bending of the lower lateral cartilage was next made raw by removing the epithelial layer. The epithelial lining was also removed from the little strip of tissue; the tissue itself was rolled up bandage-wise and then secured to the rawed surface of the pit by a stitch of the finest fishing-gut passed by a needle through the septum into the opposite nostril and back again. When thus fixed the little roll of tissue pressed out the external portion of the lateral cartilage just enough to prevent the ala during inspiration from falling into contact with the septum. It cannot be seen and produces no deformity, and, so far as the author's observation has gone, it is a permanent cure for this troublesome condition.

Some Recent Developments in the Administration of Anæsthetics.—By F. W. Hewitt. The author mentions particularly the modern employment of nitrous oxide gas succeeded by ether, and notes some of the annoyances which are occasionally experienced. The principal one arises from the sudden change from one agent to the other. Sometimes the sudden transition causes asphyxial difficulties; if the anæsthetics are gradually mixed, the channels of the inhaler through which the patient breathes are so circuitous and narrow that an unpleasant and undesirable stress is thrown upon respiration. At other times, delay is caused by measuring out doses of ether, the patient is distressed by the rushing noise of the nitrous oxide, whilst the too familiar odor of the other anæsthetic is not wholly prevented. Or, finally, the apparatus employed cannot be thoroughly cleansed after each administration. Hewitt has accordingly devised an inhaler (figured in his paper) in which the channel for the introduction of the ether is made sufficiently capacious to avoid the annoyances sometimes experienced.

A Case of Malformation.—By W. R. H. Stewart. The patient was a child who had a double hare-lip, a double cleft palate (wide and extending the whole length), and a deep central ulcer on each cornea. There were half-a-dozen supernumerary auricles scattered about the face, the largest situated just below the left extremity of the lower lip and the remainder distributed over the left side of the face and neck. On the right side the ear was represented by a much-enlarged lobule and a portion of the tragus. No sign of a meatus could be found. There was no opening through the soft tissues and no ridge or opening in the firmer structures could be felt. A portion of the premaxillary bone having been removed, both sides of the lip were closed, the whole requiring three separate operations. The space on the right side was very great, but it closed quite well. The child died on the day following the last operation. No autopsy was made, so that the real state of the ear could not be ascertained. The left ear was normal.

A Case of Temporo-Sphenoidal Abscess Following Middle-Ear Suppuration; Operation; Recovery.—By Percy Jakins. The features of the case bear out, in the opinion of the author, the view that the presence of a polypus or granulation tissue in the external meatus indicates trouble in the antrum or attic, or both, and the simple removal of the growth through the external meatus in no way touches the disease which is causing the trouble. They also illustrate another point; namely, that in cases of suppuration from the middle ear which do not yield rapidly to treatment the advisability of the radical operation should be seriously considered, with the view not only of arresting the discharge from which the patient suffers, but of preventing deeper mischief, such as cerebral abscess. Within the last two years he has operated upon four cases of cerebral abscess caused by the extension of the mischief from the middle ear.

Cases of Injury to the Epiphyseal Line.—By R. Bucknall. This series of cases comprises separation of the lower epiphysis of the humerus without displacement, separation of the epicondylo-capitellar epiphysis of the humerus, ununited separation of the epicondylo-capitellar epiphysis, partial dislocation ontward of both forearm bones at the elbow with separation of the epiphysis of the internal condyle during reduction, separation of the lower epiphysis of the radius, and separation of the epicondylo-capitellar portion of the epiphysis of the humerus.

On Generalized Infection in Gonorrhœa.—Arthur H. Ward declares that the gonococcus in its process of growth in the human body produces an irritating toxin which is the direct cause of all the symptoms of the disease. In all cases it is absorbed into the system, where its presence causes systemic degenerations of varying degrees of intensity. Gonorrhœa is thus a general toxæmic affection; but the microbes which form the toxin are commonly localized on or around a mucous tract. The microbic invasion may extend to the organs communicating with the infected tract, or it may penetrate into the tissues, either by direct exten-

sion, as in the invasion of the peritoneum through the uterus and Fallopian tubes, or by a process of growth through the mucous membrane affected. Thence the infection may invade the cellular tissues, the lymphatics and glands, and the vascular system. This invasion is possible by the action of the absorbed toxin upon the leucocytes, which is of a paralyzing nature and prevents the encapsulation of the microbes by these cells. Through the circulation the gonococci may invade the heart and endocardium, or may be carried to the peripheral capillaries. Here they may grow and form more toxin which sets up local inflammations. The microbes invade the joints, and are found in the synovial sacs, and also in the pleura and pericardium. General treatment must vary with the general conditions, and will differ according as these are referred to toxæmia alone, or to toxæmia complicated by metastases. Local treatment is always required, and should always be free from instrumental, mechanical, and chemical violence.

An Easy Operation for Congenital Ptosis.—Freeland Fergus states that any operation for ptosis must fulfil two conditions: it must be efficient for the purpose, and it must leave no cicatrices or scars. The author has employed the following method with satisfaction: A horizontal linear incision was made in the eyebrow along its whole extent (later the hairs hide the scar). The skin was completely separated from the underlying tendon and fascia of the occipito-frontalis muscle; the separation was carried to a distance of nearly two inches above the horizontal wound. In the opposite direction the skin and fascia and portions of the muscular structure were separated from the orbicularis muscle and from the tarsus, the division being carried almost to the free margin of the eyelid. Next a vertical band of the tendon and fascia of the occipito-frontalis was marked out, about three-quarters of an inch broad and two inches long. This was dissected up from all underlying structures, and when the dissection was complete, the only attachment of the band was to the occipito-frontalis at the part farthest away from the skin incision. The end of the band was drawn down into the upper eyelid, and its margin secured by catgut sutures as near the margin of the lid as possible. The wound in the skin was closed and covered with sterilized dressing. The wound healed rapidly and well.

Note on the Peculiar Nystagmus of Spasmus Nutans in Infants.—John Thomson notes some peculiar features of this form of nystagmus. It is a convergent nystagmus. As to the etiology, spasmus nutans in infants is at bottom a co-ordination neurosis. In the rotatory nystagmus of head-shaking, the eye movements are more of the nature of circumduction than pure rotation. In them the central point of the cornea passes through an ellipse or some other more or less irregular rounded figure. This nystagmus is often vertical or rotatory, instead of being nearly always horizontal. The direction of the movements is occasionally not the same in the two eyes. Lastly, it is invariably recovered from within a certain number of months.

Perigastritis and Cancer of the Head of the Pancreas Simulating an Epithelioma of the Stomach.—Grandmaison states that anorexia, cachexia, and an easily palpable epigastric tumor found in the same individual naturally suggest the idea of gastric neoplasm. The case under consideration was that of a man aged sixty-two years, very much emaciated and in a state of profound cachexia. His skin was of a dark yellow color, and his sclerotics and the inferior surface of the tongue were of a pronounced yellow tint. He took only small quantities of milk, having a complete distaste for meat. Vomiting had ceased. There was no fever. The liver was much enlarged. In palpating the abdominal muscles there could be clearly felt a tumor, irregular, rather superficial, which appeared to be connected with the stomach. There were no subclavicular glandular enlargements. The urine contained a trace of albumin. Treatment consisted in an absolute milk diet. Death ended the patient's sufferings, and autopsy revealed cancer of the pancreas. The second part of the duodenum was surrounded in great part by the head of the pancreas. This was very friable and showed in one part the discoloration characteristic of cancer. Near the junction of the head and the body of the gland there were large lymphatic ganglia showing carcinomatous degeneration. Of the three fundamental symptoms of cancer of the pancreas, only the extreme emaciation was present. Of the other two, the enormous dilatation of the gall-bladder was lacking while the dark olive-yellow tint was not sufficiently pronounced to clinch the diagnosis. Glycosuria, which is sometimes observed in the initial stage of cancer of the pancreas, was not determined. The error in diagnosis was not only inevitable but logical, since in the last days of life there were several bloody stools. The jaundice which was present could have well been accounted for by the hypothesis of a secondary generalization of cancer of the liver and bile passages. It is sometimes impossible to avoid an error of diagnosis. Errors of interpretation are often more useful in teaching a lesson than is a brilliant diagnosis.—*La Médecine Moderne*, March 18, 1901.

Epithelioma of the Internal Surface of the Cheek.—J. H. M. states that epithelioma of this part of the buccal cavity is a little rarer than that of other parts of the mouth. The etiology is very obscure. It is more frequent in man than in woman, and is observed between the ages of fifty and sixty years. Prolonged irritations and bad hygiene of the mouth may be determining causes in patients with a hereditary predisposition. The diagnosis should be early, as operation should be performed as soon as possible. The surgical treatment is the only rational one. Contraindications to operation are great extension of the neoplasm, great glandular invasion, and advanced cachexia. Such patients could be made more comfortable by palliative treatment—hygiene and antisepsis of the mouth, liquid nourishment, or soft and non-irritating foods, application of narcotics to the ulcerations, and injections of morphine.—*Journal des Praticiens*, March 16, 1901.

Berliner klinische Wochenschrift, March 18, 1901.[1]

Tenonitis Serosa.—The history of a case of this rare disease is given by Dr. Nicolai. The patient was a laundress aged fifty-two years, who had had two attacks of rheumatism leading to cardiac complications, and at the time of coming under observation for the tenonitis she had developed a double valvular murmur. On the seventeenth day of a third rheumatic attack she developed the inflammation of the eye, described under the title given by the author. This disease has been seen as an idiopathic affection, after trauma, following exposure to cold, after gout, mumps, puerperal infection, cysticercus, influenza, mercurial poisoning, and rheumatism. It is generally of a serous nature, though purulent cases have been observed, and one case on record ended in panophthalmitis. A differential diagnosis from infectious conjunctivitis is required. The structure of Tenon's capsule has a certain resemblance to that of the serous membranes, and it seems subject to the same round of infectious influences as are the latter. In general the treatment of rheumatic cases requires, in addition to the usual constitutional measures appropriate to the rheumatic condition, only light compresses wet with boric-acid solution. When the local tension in the eye threatens the delicate structures of that organ, it is appropriate to apply leeches in the general vicinity, and, if necessary, to open the capsule to prevent atrophy of the optic nerve.

Early Syphilitic Basilar Meningitis.—By E. Hoffmann. The patient was a man aged twenty-six years, who eight days after exposure developed a primary lesion, followed in eight weeks by the usual train of secondary manifestations. He was subjected to vigorous treatment and all his symptoms disappeared, though he continued to have considerable headache. At the end of three months he appeared perfectly well. Some two months later he suddenly developed symptoms of basilar meningitis. Treatment was energetically continued, and the patient recovered after an illness of about three months. The author considers the special points of interest in the case to be (1) that the disease appeared in spite of early and energetic antisyphilitic treatment continued over a period of ten weeks; (2) that the manifestations of paralysis were markedly unilateral, and (3) that there was probably a circumscribed periostitis occurring in the early period of the syphilitic inflammation of the dura mater.

Cerebral Abscess of Aural Origin.—By Dr. Stenger. A girl of eighteen years had suffered from a chronic aural

[1] This issue is in honor of the seventieth birthday of Professor von Coler.

discharge for three years. The amount of discharge had begun to increase some eight days before she came under observation. Examination revealed evidences of mastoid involvement, and the usual operation therefor was performed. Symptoms of cerebral involvement began to appear and the skull was trephined over the left temporosphenoidal lobe. Exploration with the needle revealed the existence of a cerebral abscess some distance from the brain surface. It was opened, drained, and packed with gauze in the usual manner. The patient made a good recovery.

A Noteworthy Case of Influenza Laryngitis.—Glatzel has observed a case which he reports as belonging to the category described by B. Fränkel in 1890, in which the influenza poison seems to localize itself in the larynx, producing whitish spots on the vocal cords, which as the condition progresses apparently give place to a superficial loss of substance. Fränkel suggested that the condition was probably one of fibrinous infiltration of the cords.

The Extermination of Tubercle Bacilli in Food Fats.—A. Gottstein and H. Michaelis conducted a series of observations to determine the temperature at which life becomes impossible for tubercle bacilli contained in fatty substances. It is known that the tubercle bacillus is surrounded by a waxy coating which renders it more resistant to the action of watery solutions, while it might naturally be inferred that in an oily medium this protective sheath would be dissolved and the organism be subjected to this damage as well as to the actual heating. Fats may be heated to a temperature of 87° C. without injury to their flavors; hence it is important to know whether this degree of heat is sufficient to ensure the destruction of the bacillus. By carefully controlled experiments it was shown that such is the case, even a five-minutes' exposure to this temperature rendering a fatty mixture containing virulent tubercle bacilli, harmless to the series of guinea-pigs used.

A Biological Proof of the Origin of the Albumin of Nephritic Urine from the Blood.—V. E. Mertens made the observation that human urine containing albumin gave the same reaction with "humanized" rabbit's serum as human blood, and was led to investigate the question whether such urine could be used as well as blood to prepare the serum. Two rabbits were taken, and one was prepared in the usual way by successive injections of small amounts of human blood, while the other received albuminous human urine. It was then found that the serum from either animal gave the characteristic precipitate with either human blood or nephritic urine, and also that this property was transmitted to the offspring. The assumption therefore seems justified that the serum reaction is specific for human serum albumin, and a direct proof is afforded that the albumin of the urine is a derivative of the blood.

A Contribution to the Genesis of Mastitis Adolescentium.—E. Franck is inclined to place this affection in a direct connection with the genital sphere and describes two well-marked cases in which confirmed and excessive masturbation was admitted. On abandonment of the habit the mammary condition receded. A further observation is that those addicted to this vice frequently manifest tenderness about the nipples.

The Lipochrome of the Ganglion Cells.—By M. Rothmann.

Münchener med. Wochenschrift, March 12, 1901.

The Toxicology of Arsenic.—C. Stich's observations show that in animals it is particularly the more highly specialized cells of the glandular organs and young connective tissue, and in plants the new-formed parenchyma in the neighborhood of the ducts, that undergo the first alterations in arsenical poisoning. The blood-vessels, the supporting and protective tissues of animals, and the cell walls and tube systems of plants are less susceptible. In the blood, as well as in the circulatory stream of plants, no evidence of damage as shown by coagulation is found after arsenic absorption. The ingested arsenic may be rendered gaseous; among animals certain snails, and among plants some of the molds, have this faculty. Arsenic absorbed by the fœtus through the placental circulation produces the same effects and is deposited in the same organs as in the adult.

A Case of Paralysis of the Placental Site.—A. Gerlach reports a case of this formidable post-partum complication. The patient was a primipara who was delivered with forceps and who six minutes later spontaneously expelled the placenta. There was persistent hemorrhage, although the uterus was well contracted, and the examining hand detected a boggy area corresponding to a dimpling-in of the posterior uterine wall, palpable through the abdomen. Massage, hot and cold douches, and packing the uterus were all tried in turn without effect, but the bleeding was finally controlled by ferric-chloride tampons, and the patient made an uncomplicated recovery.

Subcutaneous Paraffin Injections.—H. Meyer believes that the subcutaneous use of this agent which has been recommended by some surgeons in the closure of fistulæ, etc., is not so free from danger as its advocates assert. Experiments on animals showed that it did not remain at the site of injection, but gradually wandered through the tissues, reaching the various cavities of the body, at first by extralymphatic routes, but finally invading even these. Rabbits subjected to such injections, in the course of time exhibited serious and even fatal nutritional disturbances, which the author ascribes to blocking of the tissue channels by the material.

Alternating Mydriasis.—C. Gessner's case was that of a thirty-two-year-old woman suffering from cervical myelitis, who presented the phenomenon of alternating mydriasis. The pupils were usually unequal, but at times were dilated to the same degree, while at other times first the right and then the left would be the larger, the condition changing almost daily. The author does not think this necessarily an unfavorable sign, and states that it may be found in neurasthenia as well as in organic disease of the central nervous system.

The Treatment of Felons.—O. Schulze advises expectant treatment when necrosis exists and reports five cases in which after expulsion of the sequestrum the involucrum replaced the lost bone and union with a movable joint and useful finger resulted.

The Changes in the Bone Marrow Accompanying Leucocytosis.—H. Rubinstein counted the leucocytes of rabbits and made smears of the bone marrow obtained by resecting a rib. Some substance capable of producing leucocytosis was then injected and a second set of blood and marrow preparations made after a lapse of time varying from four hours to fourteen days. Some important observations were thus made and the author's conclusions are of great interest. (1) Leucocytosis is an exclusive function of the bone marrow. (2) After the emigration from the bone marrow of polymorphonuclear leucocytes in response to the injection of some leucocytoticum there takes place a formation of large homogeneous uninuclear cells which gradually acquire granules and thereby form myelocytes. These are the forerunners of the polymorphonuclears and undergo subsequent nuclear changes. (3) In leucocytosis of long standing the number of stored-up myelocytes may become so great as to form half of the cells present. (4) Through the formation of granules, which at first are basophile, the large homogeneous uninuclear cells develop into granular cells. (5) The development of young non-granular cells into mature granular forms takes place only in the bone marrow and not in the blood. (6) The large homogeneous uninuclear leucocytes arise from a parent form, viz., the small lymphoid elements which are found in all bone marrow. (7) These lymphoid cells of the marrow are formed on the spot and have no relationship with the lymphocytes of the lymphatic system. (8) The eosinophile leucocytes, as well as the pseudo-eosinophiles and the neutrophiles, have a common origin in the lymphoid cells of the marrow. Transitions of neutrophiles to eosinophiles are to be observed neither in the blood nor in the marrow. The author's views as to the development, by stages, of the

leucocytes in the marrow may be summarized as follows: (1) Small lymphoid cells with formed nucleus, narrow, distinctly basophile, non-granular protoplasmic area. (2) Larger lymphoid cells with larger well-formed nucleus and broad granular protoplasmic area. (3) Large lymphoid cells with a no longer distinctly formed nucleus and broad non-granular protoplasmic area, nucleus deeply staining. (4) Uninuclear non-granular leucocytes, large lymphoid cells with weakly staining round nucleus and clear non-granular protoplasm. (5) Myelocytes, uninuclear leucocytes with round nucleus and neutrophile granulated protoplasm. (6) Polymorphonuclear leucocytes with polymorphous or multiple nucleus and neutrophile granulated protoplasm. (7) The eosinophiles pass through the same stages of development with the single difference that the granules in their protoplasm are coarser from the beginning and very soon show the eosinophile instead of the neutrophile reaction.

A Case of Acromegaly.—M. A. Trachtenberg's patient was a woman aged thirty-one years, who for ten years had noticed a gradual increase in the size of her hands, feet, and face, while at the same time she was becoming stouter. For a period of several years she was much troubled by numbness of the finger tips, alternating with formication, but later this symptom subsided. Six years ago the eyesight began to grow weak, and a little later the memory became very defective, so that recent events were wholly forgotten, while what had happened during childhood was easily recollected. During the whole course of the disease she had grown progressively weaker and, of late, cardiac symptoms such as præcordial dread, palpitation, vertigo, etc., developed. On physical examination it was found that, contrary to the observations of most writers, there was no hypertrophy of the left ventricle nor accentuation of the aortic or pulmonary second sounds. A sign to which Erb's name is attached was present, viz., dulness over the upper portion of the sternum; this is thought to be due simply to the bony hypertrophy. A well-marked bitemporal hemianopsia was made out, a fact tending to support Marie's theory of hypertrophy of the hypophysis cerebri as being the cause of the lesion. It is assumed that the blood contains substances highly stimulating to growth and that it is the function of the pituitary body to neutralize these; hence when it is diseased a sort of auto-intoxication takes place, and acromegaly is therefore to be ranked with myxœdema and exophthalmic goitre. An argument against this very plausible hypothesis is the fact that the pituitary body has been found diseased in many different ways in acromegaly, both hypertrophy and atrophy having been noted, as well as new growths, yet the clinical picture is always the same.

Changes in the Chemical Composition of the Blood due to Fever.—Karl von Stejskal comments on the paucity of observations extant on the chemical changes in the blood occurring during periods of pyrexia and supplies some interesting analyses. As statistics obtained from different individuals are liable to show variations which may be purely physiological, he made his determinations on one patient who exhibited a continuous febrile movement of moderate intensity interrupted by fever-free intervals of considerable length. The physical signs pointed toward incipient pulmonary tuberculosis, though no tubercle bacilli were found in the sputum, and in addition there was present enlargement of the spleen and of the cervical and inguinal lymph glands. The specimens were obtained by venesection at the middle of a febrile and an afebrile period, respectively, the two states having in each case persisted for five or six days. As a result it was found that the fever blood as a whole had undergone diminution of its albumin and dried residue, while the water and ash were increased. Fat, cholesterin, chlorine, and iron were diminished, the calcium and potassium oxides increased, and the lecithin and sodium remained practically unchanged. Taking the serum separately, he found the most conspicuous alteration was the decrease in albumin and dried residue, with the increase of ash and water; all ether extractives were decreased, as well as the chlorides, while the potassium showed a rise. The erythrocytes were found poor in albumin, lecithin, and cholesterin, and richer in water and salts, a condition evidently indicating the imbibition of saline fluid, *i.e.*, plasma. The composition of the blood was changed in a manner to be deduced from the above, the weight of the individual red cell was raised through the absorption of plasma, while the plasma itself was diminished, with attendant reduction in albumin and gain in water and salts. The author thinks these changes referable to the temperature alone, and that other factors, such as inanition and the disease itself, may be excluded.

Aneurisms of the Aorta and Mediastinal Tumors.—P. Hampeln, in discussing the symptomatology of these two affections, lays especial stress on stenoses and pressure paralyses, the latter belonging most often to the domain of the recurrent nerves of one or both sides. Of the stenoses that of the trachea is the most important, its presence pointing strongly toward aneurism of the arch or trunk of the aorta. Out of twenty cases of tracheal stenosis eighteen were due to aneurism and only two to new growth. Of less value, because less easily recognizable, are the bronchial stenoses, which occur with aneurism or neoplasm indifferently. Œsophageal stenoses give positive evidence, but are indecisive. They more generally indicate disease of the œsophagus itself, carcinoma or stricture, and enable mediastinal difficulties in the narrower sense to be excluded. Recurrent palsies of the left side are frequently observed and have great significance. In thirty cases, aneurism was found twenty-five times and new growth five times. In doubtful cases in which other evidence is lacking, recurrent paralysis, especially if accompanied by cachexia, in those of advanced years points to new growth, while in middle age, particularly when there is a history of syphilis, aortic aneurism is also to be considered. The *x*-rays may in some instances be of great aid, though as a rule their use does not greatly facilitate the differential diagnosis between aneurism and neoplasm.

The Human Cortical Ganglion Cell as an Independent Organ.—A. Adamkiewicz, in a gracefully written article, first likens the cortex in its waking state to a mirror exposed to the light of day and reflecting all the pictures whose rays impinge upon it. This symbolizes the phenomena of consciousness, but in its ability to retain impressions and store up the images of the past to form that complex of concepts we know as experience, the mirror must also have the characteristics of the sensitive plate. But in addition to these purely reproductive faculties the cortex is possessed of creative ability, and the products of its activity during sleep we call dreams, and those of the waking state, imaginations. Experiments on the development of memory in children, and on the cerebrum itself in dogs and monkeys, have shown that experience is the result of mechanical alterations in the ganglion cells, for memory in general can be obliterated by severe concussions or mechanical injury to the brain. It is to the ganglion cell as the ultimate unit that the mental faculties as such are to be referred, and while its powers of seeing and hearing depend on its connection with the eye and ear for their relation to the outside world, these functions go on in its interior even when it is isolated, and are comprehended under the title of dreaming.

The Physical Examination of the Heart Sounds.—A. v. Holowinski, by an exceedingly complicated train of apparatus, has succeeded in photographically registering the two heart sounds and making it possible to determine the relative lengths of the silences with absolute accuracy and to plot out the waves accompanying diastole and systole. The underlying principle consists in the application to a microphone of an apparatus by which movements too small to be otherwise (even microscopically) observed are made to produce interference waves of light which may be registered on sensitive paper.

The Symptomatology and Diagnosis of Aneurism of the Aorta Perforating the Pulmonary Vessels.—By C. Hödlmoser.

The Alimentary Fluctuations in Osmotic Pressure in Man and Animals.—By F. Nagelschmidt.

Reply to Paul Edel on the Effect of Artificial Sweating on Gastric Secretion.—By A. Simon.

Intercostal Phonation.—By E. Weisz.

Archives of Pediatrics, April, 1901.

An Unusual Case of Erythema Multiforme.—Floyd M. Crandall reports a case in which the skin eruption covered every portion of the body, and over the abdomen and chest presented a mass of brilliant coloring which the writer has never seen equalled. Every peculiar form of erythema multiforme could be recognized—iris, marginatum, and annular. On the second day of the disease the throat was covered with a thick, spongy, pultaceous exudate of a grayish color, so peculiar in its appearance that the author ordered the local use of a dilute solution of peroxide of hydrogen. A few hours later the exudate had nearly cleared, the throat being still intensely congested. Altogether the attack was a peculiar one, and the inference was strong that the angina and eruption were a part of the same disease, and were the result of some unusual infection.

Duodenal Ulcer in an Infant of Ten Months.—Vanderpoel Adriance reports a case remarkable only on account of the age of the infant. The symptoms were restlessness, gastro-intestinal troubles, vomiting, constant crying, and emaciation. There was a cessation of symptoms for two weeks, and then a relapse during which the child died. Blood was vomited several times before death. The autopsy showed an ulcer of the posterior wall of the duodenum, chronic ulcerative follicular colitis, and fatty liver.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENT—MR. COUTTS AGAIN—SIR WILLIAM MACCORMAC ON SOUTH AFRICAN HOSPITALS—NATIONAL HOSPITAL DISPUTE — DISCUSSION ON IMMUNITY — DEATHS OF SIR E. SAUNDERS AND MR. BARROW.

London, March 22, 1901.

A VIOLENT attack on the war hospitals commission was made in the House of Commons on Wednesday. Of course it was Mr. Burdett-Coutts who denounced the commission and all its works in terms scarcely parliamentary. He has previously achieved the distinction of being contradicted by so many really eminent men that he might at least refrain from imputing evil motives to gentlemen whose integrity no one else has ventured to assail.

Mr. Brodrick appealed to the "common sense of the House" and asked on what grounds "these sinister motives were attributed to the commission." These independent gentlemen had, he said, nothing to gain by burking the truth, and had done an immense amount of hard work for the public. He was aware that there had been too few medical officers and of the circumstances which led to that, and he promised again that in the reorganization of the service he would do all possible to make it sufficient.

Sir Walter Foster again interposed his complaint that his advice had not been taken. It was more to the purpose to say civil surgeons had to be employed to eke out the insufficient numbers of the R.A.M.C. Last week I told you what the president of the Royal College of Physicians had to say about the army medical service. This week I have to add that the president of the Royal College of Surgeons took up the tale. Sir W. MacCormac spoke at the Hunterian Society's dinner on Friday, and clearly showed that many criticisms which had appeared were due to ignorance of the requirements of warfare. He said the army medical service had discharged their duties under the most unprecedented conditions, in a way to deserve the utmost sympathy. What shortcomings there were must be laid on other shoulders. That there was not an actual breakdown was a subject for congratulation, for eight hundred medical officers were called upon to do the work of twelve hundred. For six army corps there were only medical officers enough for two, and the service did not obtain the sympathy and support it deserved in high places, so that it could not be as efficient as it ought to be. It should, if useless, be abolished. If otherwise, it ought to be accorded high status and better pay. If these are refused, the service will continue depleted. The director-general did not occupy so good a position as that accorded to the chiefs of the service in other countries. It was necessary for the head of the medical staff to be adequately supported, and that his influence and pay should not be marked by contrast with other services. Sir William recalled that the present was not his first experience in actual warfare, and he declared that he had never seen the sick and wounded attended as well as had been the case during the present campaign in South Africa.

Sir William Church, whose speech at another society I mentioned in my last letter, repeated what he had said about the difficulties of transport and the overwork of the staff. He also defended the R.A.M.C. against the reckless charges made by irresponsible, ignorant writers.

The National Hospital dispute is again to the fore. The secretary-director has written to *The Times* a letter which the staff may well regard as an insult. He argues that the committee must be "permitted to continue their work free from those professional influences which are not always in harmony with the interests of the institution and of its patients."

That is the sort of insinuation which this official thinks becomes him, and he says recent events show the danger of letting the staff dominate the hospital. In his communication to the governors last July this very logical person asserted that two members of the staff, if admitted to the board, would dominate all its proceedings. Two would control the other ten! Again, he objected to the staff being on the committee, as they were only servants. Of course a secretary-director, well paid, is not a servant—unpaid honorary doctors are. Excellent logic!

Reading between the lines one cannot help thinking that the troubles of the hospital have all been brought about by this excessively logical secretary-director, and that the board would be well advised to dismiss him. Failing the courage to do this, the governors might save the hospital by dismissing both the board and their logical mouthpiece.

Immunity is a subject of such great extent and of so many ramifications that it is no easy matter to keep pace with its literature or to follow the numerous theories, or rather hypotheses, that are continually being brought forward. A discussion on the subject took place on the 12th inst. at the Medico-Chirurgical Society, when the bacteriologists had it much to themselves. Prof. Sims Woodhead opened it with a paper in which he recognized Metchnikoff's work as the starting-point of various theories; for upon phagocytosis depends the "side-chain theory" of immunity and antitoxin production. Dr. Sims Woodhead and Dr. Cartwright Wood, from some joint experiments, think they have obtained a condition in which special activities of the cell are drawn out, and they compare the cell to a many-faceted body, each facet being enabled to withstand the attacks of poisous which they have been trained to resist. As some properties or functions seem intimately bound up with the bodies of micro-organisms, so others are as closely connected with the protoplasm of cells. In so far as these are distinct, he held immunity to be distinct from antitoxin production, but in so far as they are interchangeable, immunity would run side by side with antitoxin production.

Dr. Woodhead then discussed the nature of antitoxin and said the views of Roux and others received support from numerous observations in its preparation. The marked local reaction of a toxin and the enormous amount of antitoxin in the blood—thousands and tens of thousands of times the quantities required to neutralize the toxin injected—seem to indicate that the immunizing or antitoxin stimulating substance is of the nature of a toxoid, or of a proteid molecule not very toxic, and that the process goes on long after the stimulus has been removed. He dissented from the idea that antitoxin is merely a modified toxin.

Professor Wright submitted that Ehrlich's theory of the production of antitoxins might perhaps apply to the production of bactericidal substances in the blood. The constituents of the bacterial protoplasm, being in many cases poisonous, pass in solution in the lymph when bacterial cultures are injected into the subcutaneous tissue. Thus, an analogy is seen between the injection of toxins and bacteria. A similar analogy exists between the antitoxin formation and the response by production of an antibacterial substance in the case of bacterial injections. Thus, the difference between an antitoxin and an antibacterial substance would be that one had an affinity for a constituent of bacterial protoplasm, the other for something contained in bacterial filtrate. Professor Wright had applied these observations to the production of antityphoid sera.

Dr. Sidney Martin, though not accepting all of Professor Wright's views, said the specific character of proteids was becoming clear, and it was now admitted that there was no reason why albuminous substances should not be poisonous to protoplasm.

Dr. James Ritchie remarked on the want of proportion between the amount of toxin introduced and the antitoxin which followed. Among the many questions still unsolved he cited: Why should the immunity once produced be increased; and how is it that the second dose is not neutralized by the antitoxin produced by the first dose?

Dr. Bokenham asked, How is it that patients are not poisoned by the bacteria found in such enormous quantities in the intestines? The liver was suggested as a guard, and he had introduced bacillus coli in quantity. He found the liver crowded with the organisms, but none in the blood on the other side, and it had been found that both organic and inorganic poisons were excreted by the bile.

Mr. Plimmer drew attention to the absurd misuses of antitoxins. They had actually been used in aneurisms. Any bacillus, he said, injected into an animal's veins would disappear in five or ten minutes. This applied to anthrax or any other organism.

Dr. William Hunter had introduced powerful hæmolytic bodies into the circulation; if the spleen were previously removed, no hæmolytic effect followed, showing that hæmolysis depended on the action of special cells of the kind found in the spleen.

Professor McFadyean, referring to the need of a definition, said Texas fever was now attributed to an animal parasite. Beasts born in a certain region were immune, but their blood contained the parasite and produced the disease when injected into a healthy animal.

Professor Woodhead, in his reply, said the malarial parasite has been found in the blood of children who seemed in perfect health. Immunity and antitoxin production seemed to go on side by side, but he agreed with Dr. Ritchie that they were not identical.

Sir Edwin Saunders died on Friday last at his Wimbledon home. For half a century he was dentist to Queen Victoria and the royal family. He was a fellow of the Royal College of Surgeons from 1855. He retired from practice some years ago, and at his death, which came after a brief illness, he had attained the ripe age of eighty-seven. He was a pioneer of the rise of modern scientific

dentistry. The Dental Hospital and School was deeply indebted to him, and his colleagues established a scholarship to commemorate his untiring zeal in promoting it. He was one of the founders, too, of the Odontological Society and twice its president. He also presided over the deutal section of the International Medical Congress in London.

The death of Mr. Barrow, J.P., who had long been an important influence in the Isle of Wight, took place on the 7th. Some of your readers will remember him as president of the British Medical Association at the meeting in the island in 1881. He died in his eighty-seventh year, universally respected.

BELLOWS INJECTION FOR INTESTINAL OBSTRUCTION.

To the Editor of the Medical Record.

Sir: I was much interested in the leading article in your January 5th nnmber on the "Prevention and Relief of Post-Operative Intestinal Obstruction," by Dr. Cleveland, which called to mind a rather amusing story told me by a well-known mining expert of the United States, Mexico, and Canada. As I recall the narrative, this gentleman was in the wilds of Western Canada examining a mineral district for an Eastern company when he fell in with a party of men engaged on a similar mission in a part of the country not far distant. In the party was an Englishman who, it seems, had suffered an attack of intestinal obstruction some years previous, dne to a twist in the bowel, for which he had been operated upon. This man suddenly developed great abdominal pain, and his abdomen became greatly distended. Upon inquiry it was learned that his bowels had not moved in several days, and he was convinced that he was now suffering from another twist, which might have been snperinduced or assisted by constipation. Various remedies were tried, including pills, castor oil, enemas, without effect. As a doctor was many miles away and separated from the sick man by almost impassable roads, my friend decided upon a plan of action suggested by the memory of the way he had seen an Irish peasant treat his cow that had eaten too heavily of green clover. He had with him a small bellows, used to create a hot flame for roasting ores, and by adjnsting the tube of a bulb syringe to this he had an apparatus by means of which he could force air into the patient's rectum. He nsed this until the sick man said he felt something give way inside his abdomen, felt his distention increasing, causiug great pain, and had an uncontrollable desire to pass gas. The tube was withdrawn, and, as a resnlt of the treatment, he expelled large quantities of gas and had a copious bowel movement. He recovered and went his way.

The story was so reasonable and so full of suggestion that I used the plan in several cases similar to those reported by Dr. Cleveland. Since the publication of Dr. Cleveland's article I have used oxygen in the way recommended and with good resnlts, bnt in no way differing from those obtained by the use of ordinary air, with the small bellows as a means of injection.

My impression is that the effect on the bowel is mechanical, and that any gas would answer the pnrpose.

The bellows should have one side of metal of snfficient weight to retain its position when the other side is drawn away from it to permit the entrance of air, so that it can be worked with one hand. The small bellows ordinarily used by assayers and metallnrgists answers very well.

The quantity of gas injected, and the speed with which the bowel is filled, can be regulated as well, or better than can be done with the oxygen apparatns, and if it is proved by further application that oxygen has no advantage over other gases as a stimulant to peristalsis, the bellows wonld be a much cheaper and far more convenient apparatus for the snrgeon, in either hospital or private practice.

Rufus McElroy, M.D.

Salt Lake City, March 25, 1901.

Treatment of Scabies.—In consequence of the use of sulphur powder for scabies being advocated by some of the members of the profession in America and in England, I have given it a sufficient test in the large out-patient department at St. John's Hospital. My clinical assistants, and other medical men who have seen the cases, agree with me that the older method of treatment by ointment is more rapid and satisfactory in its results. Four years ago I tried tobacco soap but arrived at a similar conclusion.—Alfred Eddowes.

Reviews and Notices.

Studies from the Department of Pathology of the College of Physicians and Surgeons, Columbia University. Vol. VII. New York. 1899–1900.

This is a collection of essays, reprinted from various sources, upon work done in the laboratory of the College of Physicians and Surgeons of Colnmbia University. Many of the essays are interesting, and some contain useful statistical material.

Smallpox: its Diagnosis, Treatment, Restriction, and Prevention, with a Few Remarks upon the Present Epidemic. By Louis Leroy, B.S., M.D., State Bacteriologist, Professor of Pathology and Bacteriology in Vanderbilt University, etc. Pp. 41. Issued by the Tennesee State Board of Health.

This pamphlet is of extreme interest to all interested in infectious diseases and qnarantine regulations. Not only is the disease well described in the text, bnt the numerons half-tone plates add a vividness which could have been gained by no other method. The differential diagnosis and treatment are also fully given. Copies can be had by writing to the secretary of the State board of health, Nashville, Tenn.

Formes Cliniques de la Tuberculose Pulmonaire. Classification et Description sommaire. Par Dr. L. Bard, Professeur de la Faculté de Médecine de Lyon, Professeur de Cliuique médicale à l'Université de Genève. Pp. 112. Genève: Henry Kündig, Libraire-Editeur, Librairie de l'Institut. 1901.

After reviewing the better-known classifications of pnlmonary tuberculosis and their defects the author proceeds to separate his cases into groups which he thinks will aid the practitioner in classifying his cases. His four main divisions are the parenchymatous, the interstitial, the bronchial, and the postpleuritic, and under these main headings he has the minor divisions. Dr. Bard shows throughout the work that he has had an extensive experience with the disease, and has studied his cases carefully. He acknowledges that all classifications are necessarily faulty, since one group will merge into another, but he considers it necessary for working-purposes to arrange them as best we can, and has succeeded in giving us an excellent classification.

Uterine Tumors, their Pathology and Treatment. By W. Roger Williams, Fellow of the Royal College of Surgeons. New York: William Wood & Company. 1901.

The monograph is gradually beginning to assume greater size and importance in all fields, and this example is no exception. The tumors of the uterus form such an important fraction of all pathological conditions in the organ that a volnme of the size of the present one is none too large for the subject. The author of this volume is an authority upon his specialty, consequently his views will have more weight and interest than if they had been merely compiled by some one to form a text-book. One or two chapters are devoted to a concise view of the embryology, histology, and general anatomy of the nterus, and then several chapters are occupied with the consideration of the most important non-malignant of uterine growths, the myoma. The remarks upon the course, symptoms, and complications are well worth reading; the discussion of the treatment is from the most modern point of view. Carcinoma naturally receives attention commensurate with its importance, and the various forms of operative treatment are mentioned and described with preference for the more radical procednres. The rarer forms of growth are discussed in proportion to their relative importance. A number of satisfactory illustrations have been made. The book carries out very well the monograph idea, and is an excellent addition to the modern literature of its subject.

Obstetric and Gynæcologic Nursing. By Edward P. Davis, A.M., M.D., Professor of Obstetrics in the Jefferson Medical College, Philadelphia, and in the Philadelphia Polyclinic; Obstetrician to the Jefferson and Polyclinic Hospitals; Obstetrician and Gynæcologist to the Philadelphia Hospital. Illustrated. Pp. 402. Philadelphia and London: W. B. Saunders & Co. 1901.

No nnrse who wishes to take an intelligent interest in her work can afford to allow this book to go unread. Practical and effective teaching can be found on every page. In both the obstetrical part and the gynæcological, full directions are given to the nurse regarding her duties—the various complications before, during, and after labor are all

considered; the care of the child, obstetric surgery, infant feeding, incubation, gynæcological operations, and diseases, with the duties applicable to each, are all well treated and illustrated. Both nurse and physician can profit from the sound advice which abounds throughout the book.

A Chart of the Diseases of the Heart, Blood-Vessels, Lymphatics, Blood, and Ductless Glands. Published by the M. J. Breitenbach Company, New York.

This neat wall chart comprises such points as are diagnostic in the disease mentioned in the title, arranged in parallel columns, each of which is devoted to the principal causes, general symptoms, inspection, palpation, percussion, auscultation, and blood changes, pulse, complications, and sequelæ. It is thoroughly up to date and makes a useful ready reference.

Diseases of the Heart; their Diagnosis and Treatment. By Albert Abrams, A.M., M.D., San Francisco, Consulting Physician for Diseases of the Chest, Mt. Zion Hospital and the French Hospital. Illustrated. Pp. 172. Chicago: G. P. Engelhard & Co. 1900.

The author distinctly disclaims writing a treatise on heart disease, and mentions as his object in publishing the work simply a desire to point out valuable hints along with the usual symptoms such as would be valuable to the practising physician. In this he has succeeded, for the book is a useful synopsis of the common diseases of the heart and arteries, and is especially valuable as an aid in diagnosis. Although rather too concise, the author has used his space to advantage, and is clear in description and sound in teaching.

Physical Diagnosis in Obstetrics. A Guide in Antepartum, Partum, and Postpartum Examinations for the Use of Physicians and Undergraduates. By Edward A. Ayers, M.D., Professor of Obstetrics in the New York Polyclinic, Attending Physician to the Mothers' and Babies' Hospital. With illustrations. Pp. 283. New York: E. B. Treat & Co. 1901.

The author lays special stress on antepartum diagnosis, so that accidents being foreseen may be better averted. With this object in view he is especially thorough in his descriptions of history-taking and physical examination. In fact the book may be considered an excellent guide to one learning scientific obstetrics, in that each point is separately taken up, discussed, and decided for the reader. Over sixty illustrations elucidate the text.

Enteroclysis, Hypodermoclysis, and Infusion: a Manual for Physicians and Students, with a Chapter on the Carbonated Bath and Some New Applications; also Therapeutic Addenda. By Robert Coleman Kemp, M.D. Pp. 347. New York: James T. Dougherty.

This work is an exceedingly practical exposition of the modern methods which are used in connection with shock, hemorrhage, intestinal derangements, etc. The technique is described fully, the amount of fluid and the frequency of administration, together with the temperatures and different fluids to be employed. Dr. W. H. Thomson has written the introduction, which is followed by Dr. Kemp's articles on enteroclysis and hypodermoclysis, and Dr. R. H. M. Dawbarn's treatises on infusion, shock, and anæsthesia, the volume concluding with Dr. Kemp's article on carbonated baths and other therapeutic measures. The working-knowledge which the reader obtains from the text is so valuable that it compels him to forgive the typographical errors. There are over seventy-five illustrations which are most helpful and practical.

American Text-Book of Physiology. Edited by William H. Howell, Ph.D., M.D., Professor of Physiology in Johns Hopkins University. Vol. II., royal octavo, of nearly 600 pages, fully illustrated. Philadelphia and London: W. B. Saunders & Co. 1900.

The second volume of this excellent text-book merits the highest approbation, and the whole work may be considered one of the best ever published. In the second edition we note that the most recent advances in the knowledge of the subjects treated have been added; especially is this true with reference to the central nervous system which subject has been wholly rewritten. The General Physiology of Muscle and Nerve and of the Special Muscular Mechanisms is treated by Warren P. Lombard, the Central Nervous System by Henry H. Donaldson, the Special Senses by Henry P. Bowditch, with the exception of the Ear and Hearing by Henry Sewall, and the final article on Reproduction by Frederic S. Lee. Each and every subject is treated by those well adapted for the work, and incorporates practically all that is useful and accredited in the domain of physiology.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 4, 1901.

George L. Peabody, M.D., Vice-President, in the Chair.

The Duty of the Public to the Medical Profession.—Dr. D. B. St. John Roosa presented the first paper on this subject (see page 521).

Dr. William H. Thomson contributed the second paper on this topic. He discussed some of the causes why the public did not appreciate as it should the work of the medical profession. One of the most important of these he declared to be the conception that the practice of medicine was nothing more than a trade, a means of getting a livelihood. Another cause was the erroneous but widespread belief that the medical profession was a particularly close and selfish corporation, jealous of all rivals and hostile to all new methods of treatment that might by any chance rob them of their business. This and other misconceptions arose from a remarkable ignorance of medicine and a general belief among the laity that physicians really knew little more than they did themselves about disease. The most intelligent and well-educated people in other matters did not hesitate to come to the physician with their own ready-made diagnoses of their ailments. It should be known at the present time that medicine made no haphazard or accidental discoveries, because of the world-wide international brotherhood of science. All modern discoveries in medicine were the result of patient, systematic, and laborious research. As medical knowledge had become more and more based on facts, it had become a matter of necessity for physicians to devote themselves to specialties. It was an utter impossibility for the most erudite and experienced physicians of the present day to know more than one-quarter of what was known about the human body in health and disease. Dr. Thomson put in an earnest plea for the teaching of anatomy and physiology to both sexes in every high school and academy in our land. To know something about one's own body should certainly be a part of a liberal education. By this he did not mean that people generally should be taught in the schools anything of the practice of medicine, but only that just as they are taught in the schools enough of astronomy to enable them to see the absurdities of astrology, so they should be taught enough about anatomy, physiology, and hygiene to make them appreciate the falsity of the claims and pretensions of quacks and charlatans. But one could not wait for such a change in our system of education, as we were confronted now by an emergency—the specious claims of those who called themselves both Christian and scientists. Physicians could hardly be surprised by the absurd claims of these people, nor need they be troubled about them were it not that, without proper restrictive legislation, the public health was jeopardized.

Public Enlightenment on Things Medical.—Dr. Andrew H. Smith said that the last two decades had witnessed an unexampled advance in the practice of medicine and surgery, while the popular mind had been, strangely enough, showing a strong tendency to go back to the superstitions and traditions in the medicine of mediæval times. The public seemed to be about as much impressed by the claims of the Christian scientists and osteopaths as by the wonderful achievements of scientific medicine in the closing years of the nineteenth century. That the blame attached to the medical profession for this anomalous

situation it seemed to him could not be denied. They must plead guilty to sins of omission in neglecting systematically to keep the public informed as to what had been actually accomplished by the science of medicine. In other branches of science the utmost publicity was given to each new discovery, and these were explained in popular language. Attempts to inform the public in a popular way on medical topics were generally frowned upon as thinly veiled advertising. The Christian scientists had not done this, but, on the contrary, had given the greatest publicity to their teachings. An intelligent comprehension of what medicine had accomplished and what it aimed to accomplish would remove a great deal of popular misapprehension. Medical consultations were still carried on in secret, and even a dead language was used in the writing of prescriptions. The world had a right to know, and it was our duty to tell, just what progress we were making day by day. A frank and open course would command confidence, silence criticism, and later put the charlatans to confusion.

Dr. Frederic R. Sturgis said that until a very short time ago medical education was a private enterprise. At present but few schools followed this course, being attached to general colleges or universities, although, after all, these were really private enterprises. Medical services were certainly at present largely gratuitous, but the benefit therefrom to the individuals and to the public was not apparent—indeed, it was a direct detriment to the public. He believed the medical profession did a vast deal of harm by teaching the public to be paupers. The plan of teaching physiology in the schools had been tried within the last few years in accordance with a legislative enactment, yet pupils and teachers had with one accord pronounced the plan a failure.

Dr. A. Jacobi cited the cases of Lieutenant Hobson and General Funston as examples of how promptly and how keenly the public appreciated deeds which it understood, or thought it understood, and he insisted that the reason the achievements of medical science were not appreciated by the public was that they were not understood. It had been charged that the medical profession kept the public in ignorance of medical matters, and this was true; but whether we should enlighten the laity on such subjects through the newspapers was another matter. Unhappily the public knew that there were quacks and fakes even among the ranks of the medical profession, and hence they distrusted them all as a class. Such doings bred contempt, and it took a long time to overcome the feeling of resentment thus engendered. Regarding the "Bell" bill, he would say that, for every letter sent to the legislature by a physician, at least thirty had been sent by the Christian scientists and osteopaths and their sympathizers. The profession of medicine kept altogether too much aloof from the public, and this lack of interest in public sanitation certainly did not lead the public to take an interest in the medical profession. The physician was too apt to become engrossed in his individual business and neglect his duties as a citizen.

Dr. G. L. Peabody thought the public lost sight of the fact that physicians were really agents intended to do a most important work for them. Physicians existed because there was a demand for them, and he thought the public obtained rather better physicians than it demanded, estimated by what it paid for the services so rendered. From the fees paid to most general practitioners in the country he believed that what the public wanted was a large supply of rather poor doctors. Physicians should take pains to explain that the medical profession was not a trades union, and that whatever redounded to the good of medical education or to the medical profession would redound to the good of the public.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, March 28, 1901.

A. Brothers, M.D., Chairman.

New Instruments.—Dr. A. H. Goelet exhibited a combined uterine dressing-forceps and placental forceps having a very firm grip, and useful in the treatment of abortions. He also presented a universal retractor, chiefly of use in operations on the kidney and round ligament. It was large at one end and small at the other.

Firm Adhesions in an Alexander Operation.—Dr. Goelet then reported the following case: The patient had come to him last spring with what had appeared to be a retroverted uterus. He had inserted a pessary and had advised operation. When next seen, quite recently, she had consented to operation. On attempting to do an Alexander operation he had been unable to find and pull out distinct portions of the round ligaments, and had consequently done an abdominal section. He had then discovered dense adhesions between the posterior part of the fundus and the rectum. With great difficulty these had been separated and the uterus brought forward and suspended from the abdominal wall. He had never before met with such adhesions in the canal, and thought they probably explained some of the causes of failure in the operation for shortening the round ligaments.

Dr. G. M. Edebohls said that this condition was not very uncommon; he had met with fifteen or more such cases. The proper thing to do under such circumstances was to open the internal ring on either side instead of making a median incision. This would allow of easily liberating the adhesions, when the round ligaments could be shortened in the usual way. Occasionally these adhesions would re-form, and if this occurred the uterus would be drawn backward again.

Dr. H. J. Boldt said that he too had met with quite a number of cases in which these adhesions had been present, but he had never observed any re-formation of the adhesions.

Fibromyomata of the Uterus.—Dr. H. J. Boldt presented three fibromyomatous uteri removed by total abdominal hysterectomy. None of the women had had children, and because of the smallness of the outlet he preferred the abdominal route. Although there was profuse menstruation in each instance, in only one was the operation undertaken because of the profuse loss of blood; the different forms of internal medication used to control the profuse flow, as thyroid extract, mammary extract, hydrastis, and ergot, proving inefficacious in this instance. In the case of the other two patients the specimens demonstrated very well the pressure symptoms which the neoplasms produced. The latter were tightly wedged in the pelvic cavity, and the tumors produced obstinate constipation by mechanical obstruction, in addition to the pelvic pain and the pain radiating down the thighs. Further he demonstrated four dermoid ovarian cystomata. In each instance, pain was a prominent feature. The largest tumor filled the pelvis and abdomen up to the umbilicus. This tumor was removed by the abdominal route. The three smaller dermoids, varying in the fresh state from 5 to 7 cm. in diameter, were removed per vaginam. In the case of one patient the soiling of the pelvis by some of the contents of the neoplasm produced a pelveoperitonitis from which the patient suffered nearly two months. The other patients made uneventful recoveries.

Dr. Boldt next showed a specimen of primary carcinoma of the Fallopian tube. This was the most interesting specimen, and the patient from whom it was removed presented unusual features in the history. She was operated upon four years ago for supposed tubal

inflammation. The age of the patient was at that time thirty-seven years. She complained of so much pelvic pain that salpingo-oöphorectomy was decided upon. The uterus was freely movable. Microscopical examination of the specimen determined its carcinomatous nature. She made an uninterrupted recovery, and he neither saw nor heard anything of her again until two days ago, when she presented herself, complaining of much pelvic pain and a typical sanguineous discharge. Examination showed an inoperable carcinoma. It is probable that the recurrence took place in the uterine cornua, although at the time of the operation, four years ago, absolutely nothing of a suspicious nature was found.

Dr. J. E. Janvrin said that he had had one similar case of carcinoma involving the whole tube, and beginning in it; also two cases of carcinoma developing in the folds of the broad ligament.

Dr. George M. Edebohls presented the specimens and related the histories of the following cases:

1. Abdominal total extirpation of the four-months pregnant uterus; resection of 18 cm. of the rectum and sigmoid for carcinoma; end-to-end anastomosis of sigmoid and rectum; all successfully performed at one sitting. The patient, the uterus with the four-months' fœtus *in situ*, and the resected piece of sigmoid and rectum, were presented, and the following history was narrated: Mrs. E. K——, a married woman aged thirty-four years, mother of five children, and again pregnant in the fourth month, was sent to him by Dr. George A. Leitner, of Piermont, N. Y., for the removal of an operable cancer of the rectum, which, according to her history, had existed for three to four months past. Examination showed a tumor mass occupying the upper end of the rectum and the lower end of the sigmoid, and confirmed the existence of a pregnancy of four months. The lower end of the cancer was nearly five inches from the anus; the bowel and the tumor were fairly movable upon the surrounding parts; there was, however, almost complete obstruction, with large accumulation of fecal matter above the tumor. To overcome the necessity for a Kraske operation, Dr. Edebohls planned and executed an operation, original with himself as far as his knowledge went, the essentials of which consisted in hysterectomy, resection of the carcinomatous bowel, and end-to-end anastomosis of the sigmoid and rectum, all performed at one sitting through an anterior abdominal incision. After thorough dilatation of the anal sphincter and tamponade of the cleansed vagina with iodoform gauze, the abdomen was opened by a 15-cm. incision carried through the left rectus abdominis muscle. The large uterus with the contained fœtus was removed in one piece with both tubes and ovaries—a typical panhysterectomy. Eighteen centimetres of bowel were resected, embracing 8 cm. containing the cancerous mass situated at the junction of sigmoid and rectum, together with about 7 cm. of healthy bowel above and about 3 cm. of healthy bowel below the tumor. Removal of the sacral glands and of all fatty and connective tissue posterior to the resected bowel was followed by end-to-end anastomosis of the sigmoid with the rectum, the sigmoid being invaginated into the rectum and the invagination maintained by two rows of interrupted sutures of ten-day catgut, twenty sutures in each row. A small strip of gauze was adjusted about the bowel at the line of suture and the end led into the upper end of the vagina. The abdominal incision was tightly closed. Free evacuation of the bowels occurred soon after operation. Convalescence was uneventful, with primary union of the wounds of the abdominal wall and bowels. The operation was performed on February 26, 1901. Fifteen days later the patient left her bed. It was, of course, too early to speak of ultimate results; the immediate results certainly approximated the ideal. Microscopical examination of the tumor, made by Dr. Henry T. Brooks, proved it to be an adenocarcinoma.

2. Large hydronephrotic kidney removed per abdomen; radical operation of ventral hernia extending from sternum to pubis, and inversion of the appendix for chronic appendicitis performed at one sitting; recovery. I. S——, a married woman aged thirty-eight years, mother of six children, had first noticed a fulness in the right groin and lumbar region twelve years ago. The further growth of the tumor was characterized by attacks of cramp-like pains. During each pregnancy the tumor would recede and the pains disappear, only to become greater after delivery. When first seen the fluctuating tumor entirely filled the abdomen, stretching the tissues over the central parts to paper-like tenuity. The characteristic lobulations were plain to the sight and touch. The recti abdominis muscles were separated fully 20 cm. at and near the umbilicus, large portions of the tumor projecting between them in the form of a hernia, and practically becoming subcutaneous. The operation was performed March 22, 1901. An incision was made in the median line from sternum to pubis, with a view to radical cure of the hernia and, secondarily, to permit of removal of the huge cyst unbroken. The tumor proved to be a right hydronephrosis. The posterior layer of parietal peritoneum covering it was incised to the outer side of the ascending colon; the ureter and a number of very large vessels were tied off, and the tumor was peeled out and removed without tapping or rupture. The vermiform appendix was found enlarged and thickened to more than twice its normal size, by chronic inflammation. It was inverted entire and unopened. A strip of skin and attenuated fascia, 10 to 12 cm. wide, including the umbilicus and extending the whole length of the incision, was resected so as to render possible approximation of the widely separated recti muscles. The sheath of each rectus was opened along its mesial aspect and the abdominal wall was repaired by uniting to each other, in succession, the posterior sheaths, the muscles themselves, and the anterior sheaths. The tumor after removal weighed 6,800 gm. (15 pounds). It was ovoid in shape, measuring 84 cm. over its largest and 72 cm. over its smallest circumference.

The enormous size of the tumor and the extensive radical herniotomy constituted the features of interest in the case. Dr. Edebohls added that he had thus far removed four large hydronephrotic tumors through the anterior abdominal incision, all of the patients making good recoveries.

Dr. Bache Emmet said that he had had a case of a similar cyst of the kidney, which had also been removed through the anterior incision. The case was interesting because the woman had returned this winter, after an interval of four or five years, with another tumor spreading from the pedicle. The record of the nature of the first growth had been lost, but there was a reasonable suspicion of malignancy.

Dr. Paul F. Mundé said that some years ago he had removed a similar tumor which had protruded through the anterior abdominal wall. It had proved to be a malignant growth of the kidney of about the size of the one in Dr. Edebohls' case.

Fibroma (?) of the Ovary.—Dr. Bache Emmet presented a tumor that had been removed from a woman of forty-six, who had been menstruating rather freely. The mass had been growing quite rapidly in the past few months. The tumor consisted of a gelatinous mass which gave the impression to the examining finger of an ovarian cyst. The first incision had unexpectedly opened into the bladder, and further exploration had shown that this viscus was attached to the tumor far up in the median line. It was covered

with an extra layer of the peritoneum of the broad ligament, and from this he assumed that the mass was a tumor, probably a fibroma, of the right ovary. The left ovary had been found.

Dr. Boldt said that the appearance of this fresh specimen made him think it was a fibrosarcoma of the ovary.

Dr. A. Brothers said that he had presented about one year ago a fibrosarcoma of the ovary of the size of a cocoanut. He had seen a smaller one since then.

Dr. Mundé said that about twelve years ago he had removed a large fibroma of the ovary. The specimen just presented appeared to be a fibromyoma.

Sactosalpinx Hæmorrhagica.—Dr. Ralph Waldo read a paper with this title. He said that these cases included all accumulations in the Fallopian tube not due to pregnancy in the affected tube. E. Simon had collected 70 cases of atresia, 51 of which were congenital and 19 acquired. Of the 19, 8 had occurred after abortion, 2 had been due to traumatism, and 5 to infectious diseases. Of these patients 22 had sactosalpinx hæmorrhagica, and 14 had died. Several prominent surgeons were of the opinion that all cases of hæmatosalpinx were not due to extrauterine pregnancy. Dr. Waldo then reported two cases of sactosalpinx upon which he had operated. The first of these was that of Mrs. J. P——, who had been admitted to the Lebanon Hospital on December 12, 1900. She had menstruated regularly since the age of fourteen years, and she had on admission pain localized in the right side of the abdomen. She had come to the hospital with a diagnosis of appendicitis. Her temperature was 102° F.; pulse, 108; and respiration, 20. Examination had revealed a tumor low down in the right iliac fossa, and the muscular rigidity had not been so great as one would expect in a case of appendicitis. She had begun to menstruate on December 11th. The abdomen was opened, and a dark globular tumor, four or five inches in diameter, had been found low down anteriorly and above the right broad ligament, extending to the median line. It was slightly adherent to the neighboring structures, including the appendix. The pedicle of this tumor was only half an inch in diameter. There was no free blood in the peritoneal cavity, but there was quite an extensive peritonitis. The pedicle was found to be twisted and strangulated. The tumor consisted of a markedly dilated Fallopian tube which had been completely strangulated near the uterine end by several complete twists in this portion. The contents were entirely dark fluid without coagula. Microscopical examination had shown no evidence of extra-uterine pregnancy. The patient died of pneumonia seven days after the operation, but no autopsy could be obtained. The second case was that of Mrs. R——, forty-six years of age, admitted on December 17, 1900. She had been well up to three months previously, and since then had had considerable pain low down in the abdomen. On admission, her temperature had been 101° F.; pulse, 116; and respiration, 28. On examination an immovable, slightly fluctuating tumor was found, extending from the symphysis pubis to the umbilicus. She had had a slight range of temperature for the next ten days, but the pain in the left iliac fossa diminished. Pain on urination was severe. On January 10, 1901, an incision had been made in the median line and a dark, globular, fluctuating tumor exposed. It was extensively adherent to the neighboring structures. The ovary was not involved, and the tumor consisted of the Fallopian tube occluded by several distinct twists. There was no free blood in the peritoneal cavity. The fimbriated extremity of the tube was entirely closed by an old inflammatory process, and the uterine end by twists in the tube. The tube was filled with dark fluid without clots. The specimens from both these cases were presented. The fluidity of the blood contained in the tubes was in marked contrast with the clots usually found in ectopic gestation.

Early Diagnosis of Ectopic Gestation.—Dr. A. F. Currier read a paper on this subject. He said that rupture of the tubal tumor usually occurred before the end of the first three months. Of the ordinary symptoms of pregnancy, one should note the enlarged veins and papillæ of the breasts, the darkened areola, the blueness of the vagina, and the softness of the cervix. The presence of retroflexion, sterility, dislocation or twisting of the Fallopian tubes, all favored the occurrence of ectopic gestation. The most important sign was hemorrhage, which occurred earliest in cases in which the gestation was situated near the distal extremity of the tube. A fœtal sac at the fimbriated extremity rarely went on longer than the end of the first month, without rupture. In other situations, rupture usually occurred between the sixth and twelfth weeks. Next to bleeding as a diagnostic symptom was sharp, darting pain in the abdomen. The third diagnostic point was the presence of a tumor, and this could be best determined by examination under an anæsthetic. The passing of decidual membrane from the vagina, and hemorrhage from the uterus, were not constant, and were of doubtful importance. The diagnosis of tubal gestation was not always conclusive even after the abdomen had been opened. Without a decidua, whether within the uterus or within the tube, there could be no gestation.

Dr. Mundé said that he had never seen a case in which twists of the Fallopian tube had produced a hæmatosalpinx; hence the interest attaching to Dr. Waldo's report of two such cases. He had ordinarily not found it very difficult to make a diagnosis of ectopic pregnancy up to the third month, provided there was a reasonably clear history. After rupture, the diagnosis was certainly not difficult in most instances. Cases were cited to show the difficulties of diagnosis in certain classes of cases. In a tubal abortion the hemorrhage was slower and the symptoms consequently were less urgent than in rupture of the tube in its calibre.

Dr. Bache Emmet touched upon the pathology of ectopic gestation, commenting upon the present tendency to seek for the first changes in the mucous membrane rather than in the peritoneum. It was probable that a gonorrhœa was often responsible for the first changes in the mucous membrane, which eventually led to obstruction of the calibre of the tube. There were possibilities of error in diagnosis, arising from various forms of flexion or version of the uterus.

Dr. Janvrin said that fourteen years ago he had read a paper on this very subject of the early diagnosis of extra-uterine pregnancy, and had reported a case in which he had diagnosed a tubal pregnancy in the first few weeks and had treated it by three applications of the galvanic current. Shortly after the third application of electricity the patient had suddenly gone into collapse and died, and the post-mortem examination had shown that rupture of one artery supplying the gestation sac had been the cause of the fatal hemorrhage. Since then he had given this subject much study, and had recommended an exploratory laparotomy, though not knowing at that time that the operation had been advised in these cases previously. Irregular menstruation, colicky pains in the abdomen, and an extremely tender tumor outside of the uterus were the chief diagnostic points before rupture. It was a question whether many cases reported as tubal abortions were not really examples of the class of cases reported by Dr. Waldo this evening. He had never met with any case of twisting of the Fallopian tube. Twisting of this tube should cause more or less twisting of the broad ligament, and was certainly a

most remarkable condition, and one difficult of explanation.

Dr. E. H. Grandin said that when the symptoms of extra-uterine pregnancy, such as had been outlined in Dr. Currier's paper, were present, it should be an easy matter to make the diagnosis. He had seen a fairly large number of cases, yet he must admit it had ordinarily been a matter of guesswork. From the middle of last August to the present time he had operated upon seven cases of extra-uterine pregnancy. In six of the cases the belly had been full of clots; in the seventh, the blood in the peritoneal cavity had come from the rupture of a large Graafian follicle. In none of these cases had there been enlargement of the uterus; in one there had been a decidua, the only case of the kind that he had met with in all the cases of ectopic gestation that he had seen. In these cases he had guessed at the diagnosis because of irregular menstruation, colicky pains, and the presence of a tender mass at the side of the uterus, and he had confirmed the diagnosis by posterior vaginal section. He was of the opinion that every woman who presented symptoms which were at all atypical as regards the menstrual period, and which were associated with a "green-apple colic," should be subjected to a posterior vaginal section. If this were done aseptically the woman would be none the worse for it, and if blood and clots were not evacuated an opportunity would be afforded for palpation of the uterus and its appendages.

Dr. H. J. Boldt said that he had been unable to find evidences of ectopic gestation in two or three cases of hæmatosalpinx that he had had, but he could not conceive how it was possible for the Fallopian tube to undergo twisting, either alone or with the broad ligament. It had been maintained by some that a salpingitis played no rôle whatever in the production of ectopic gestation. He had himself met with recurrent ectopic gestation five times, and in each one of these five patients he had demonstrated at the first operation the existence of an inflammatory condition of the other Fallopian tube. Hoping that this would disappear spontaneously he had allowed the tube to remain, with the result that the tube had become the seat of an ectopic gestation within a year. He personally believed that salpingitis did play an important part in the production of tubal gestation. He had seen in tubal rupture periodical discharges of blood, though the rule laid down by Dr. Mundé regarding the relative profuseness of the hemorrhage in this and in tubal abortion generally held good. Some patients gave a typical history of ectopic gestation, and the local condition seemed to confirm this, and yet operation showed that there was no ectopic pregnancy present.

Dr. Waldo said that in his first case the tube had been high and the broad ligament partially twisted. The tube had been distinctly twisted, and had drawn the ovary up with it. In the second case the tumor had been easily removed without being ruptured. He had searched the literature of this subject fairly well, and had been able to find only one other apparently authentic case—one reported by Dr. W. W. Russell, with a photograph, from the service of Dr. Howard A. Kelly. This case had been reported under the name of hemorrhagic infarction of the tube.

Dr. Currier, in closing, laid great stress upon the importance of bearing in mind that pregnancy, whether normal or abnormal, had certain signs after the second or third month, which were unequivocal. If these were looked for they would usually be found, and would materially aid in making the diagnosis in this difficult class of cases. He believed that the diagnosis could be made in many cases with fair accuracy, provided the examination was made under a general anæsthetic.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 18, 1901.

Parker Syms, M.D., President.

Primary Carcinoma of the Tip of the Appendix.—Dr. J. Riddle Goffe presented this specimen, which had been taken from a well-nourished girl aged seventeen years, who had complained of nothing but a chronic appendicitis of low grade for a year and a half. At the operation a small spherical mass had been found in the tip of the appendix, resembling a calculus. After removal it had been found that this mass could be shelled out, and that it had lain between the muscular coat and the peritoneum. Specimens from the tumor and from the adjacent tissues of the appendix were exhibited under the microscope. The pathologist found an acute appendicitis throughout the organ, and that the mass referred to, presented the typical structure of a carcinoma. The grandmother of this girl had been subjected to a hysterectomy for cancer of the uterus, four years ago. There was, however, no other history of cancer in the family. The growth appeared to be primary in the appendix.

Primary Carcinoma of the Sphincter Muscle of the Bladder.—Dr. Goffe also presented this specimen, which had been taken from an unmarried woman, twenty-seven years of age. She had been kept under observation for three weeks, and in this way a small circumscribed hardening had been eventually detected in the sphincter muscle on the left side of the bladder. When this growth had been cut down upon, it had been found disseminated in the muscle and intimately adherent to the mucous membrane. Prior to the operation the woman had been greatly annoyed by frequent micturition; but the operation had given complete relief, and healing had been perfectly satisfactory. On microscopical examination, Dr. F. M. Jeffries had reported the growth to be a carcinoma.

Operative Treatment of Hemorrhoids.—Dr. William Duff Bullard read this paper. He was of the opinion that there were only four operative methods of treating hemorrhoids, worthy of the name. They were: (1) The injection method; (2) the Whitehead operation; (3) the ligature operation; (4) the clamp-and-cautery operation.

Injections.—He had had no experience with the injection method, and did not expect to have so long as there were other and so much better ones at his disposal. From five to thirty drops of the chosen solution were injected into the mass at a time, and the patient was told to return in a few days for another treatment. This method seemed to be a part of the stock in trade of charlatans, and in the majority of cases, if cleverly done, it would give temporary relief without preventing the patient from continuing at work. The object was to secure contraction of the blood-vessels and adhesions between the mucous membrane and the submucosa. The veins of this region were very large and easily ruptured. Obliteration of the cellular spaces was what was aimed at, whether the fluid employed for the injection was bland or irritating. The adhesions would persist for a certain length of time, and so give temporary relief. Occasionally, small and very painful abscesses would form at the anal region, and would leave behind a granulating surface and a small superficial fistula. If the injection was made a little too deeply, a spreading inflammation was apt to result. Sometimes the injection caused a slough and the formation of a rectal ulcer. In some instances this might lead to the formation of a stricture, although some writers insisted that such inflammation might even go further, resulting in pyæmia and possibly death. He had not been able to find any well-authenticated case of death from this cause.

Whitehead's Operation.—This consisted in the denudation of the pile-bearing area of the rectum. The operation was difficult, particularly in view of the fact that, to secure a good result, primary union must be obtained. One of the sutures was apt to pull out during a paroxysm of coughing or vomiting, or in the act of defecation, and when a suture gave way in this manner an ulcer resulted. The operation was followed by many mishaps, but was not done nearly so often at the present day as a few years ago.

The Ligature Operation.—In this operation the sphincter was first dilated with the fingers, and then the hemorrhoids were allowed to prolapse. The piles on the posterior wall close to the anus should be first ligated. If the base of the pile was large, the hemorrhoid should be cut loose from the skin and subcutaneous tissue, the cut being made in a line parallel to the longitudinal axis of the gut. Silk was preferable for the ligature, though catgut, which would not be absorbed for two weeks, might be used. The hemorrhoid should not be cut off too close to the ligature. The patient was kept in bed until the ligatures came away, which usually occurred in about one week. The bowels should be kept from moving for two or three days by the use of morphine, and the patient should be warned that there would be some pain for the first few days, and that the first movement of the bowel would be accompanied by the passage of some blood.

Clamp-and-Cautery Operation.—In this operation the hemorrhoid was seized with the clamp, the hemorrhoid cut off, and the stump seared with a hot iron. A thick eschar should be left, and it should lie in the longitudinal axis of the bowel. Any number of grasps of the clamp might be made if this rule were observed, but three would usually be found sufficient. In the ligature operation the sutures caused irritation and tenesmus, and the convalescence was more prolonged than when the clamp was used. Patients treated by the clamp were out of bed, as a rule, in five days. The speaker said that he had never seen any secondary hemorrhage follow the use of the clamp. He was disposed to think that the ligature operation was a little more liable to be followed by a recurrence than the clamp operation. He would unreservedly condemn the injection method and the Whitehead operation.

Injection Method Often Useful.—Dr. James P. Tuttle thoroughly indorsed all that had been said with regard to the success and general adaptability of the ligature and of the clamp and cautery operations. He thought the palliative treatment of hemorrhoids was too much neglected at the present day in our enthusiasm over radical surgical procedures. He asserted that there was a large number of cases of hemorrhoids which, if not too far advanced, would result in radical cure by proper local treatment associated with judicious regulation of the diet and general hygiene. When hemorrhoids had been bleeding and prolapsing for only a short time, if the sphincter was gradually dilated on alternate days with a bougie and the patient instructed to use cold applications and astringent injections, such as krameria, very great benefit would accrue from such simple treatment. The speaker criticised the statements in the paper on the ground that as the author had had no experience with the injection method, he was not in a position to condemn it. Dr. Tuttle said that he had employed the injection method in many cases with success, and while he had in a very few instances met with a slough, it had done no harm; moreover, just such accidents were frequently observed with the ligature or with the clamp-and-cautery operation. If the injections were given with proper aseptic precautions, there should be no danger of abscess or of sepsis. He did not believe in the injection method for all cases, but it certainly was very useful in certain forms of hemorrhoids. The reason that unfortunate results had followed injections, the Whitehead operation, and the others was that there was no perfectly satisfactory method for all hemorrhoids. In doing the Whitehead operation it was necessary to take off only the lower portion. The error was often commited of taking off the tissue too deeply.

Ligature Operation under Local Anæsthesia.—Dr. John F. Erdmann said that he coincided thoroughly with the reader of the paper regarding the injection method and the Whitehead operation. He had used the injection method in several cases, but had felt that the pain incident to the use of the injection needle was no greater than would be experienced from the injection of cocaine and eucaine, and if the latter were done a more radical operation would be possible. He had used both the ligature and the clamp operation, but preferred the former. He saw no necessity for keeping the patient in bed any longer after the ligature operation than after the use of the clamp and cautery. With both operations there was a slough of the tissues, and all that the surgeon waited for was the formation of a clot in order to insure against secondary hemorrhage. Such hemorrhage he had known to occur in connection with both the ligature and the clamp operations. When there was much pain after the ligature operation it was usually because the hemorrhoid had been cut off too close. An operator in Cincinnati had suggested an excellent modification, *i.e.*, the sewing of the mucous membrane over the ligature. There was no question about the Whitehead operation being followed by stricture more frequently than were the other methods, but he had seen a very bad stricture after the clamp operation, done by one who was by no means a novice.

Dr. J. Riddle Goffe thought that stricture was liable to occur with both the ligature and the clamp operation. He was sorry to hear the Whitehead operation so strongly condemned, because if care was taken not to remove any more than the pile-bearing area there should be no untoward result. It was his own practice to use four sustaining sutures, and he had had no unpleasant complications since adopting this plan.

Dr. Bullard, in closing the discussion, said that he had not unreservedly condemned the injection method, but only the Whitehead operation. The latter seemed to him a most difficult and wholly unnecessary operation. It was impossible to secure asepsis in the rectum for any length of time, and yet one must do this in order to secure primary union. The application of the cautery was a great safeguard against sepsis.

Arteriosclerosis.—Dr. Isaac Adler read a paper on this subject. He said that the very term arteriosclerosis had by no means a stable and generally accepted signification. Arteriosclerosis had been very generally looked upon as a disease primarily of the media coat of the blood-vessels. While very many of the prominent phenomena were undoubtedly accounted for by Thoma's theory, it did not explain them all. His theory provided a sufficient explanation for the lesions in the larger and in the largest vessels, but he did not think it sufficiently accounted for the alterations in the smallest vessels and in the parenchyma. It seemed to be a demonstrated fact that in every instance of arteriosclerosis the process was not confined to the blood-vessels alone, but the organ and tissues participated in the form of a hyperplasia, ultimately leading to circumscribed or diffused fibrosis. Every arteriosclerotic vessel seemed to be associated with more or less complete fibrous induration of the territory which it supplied. It was probable that arteriosclerosis often began in the smallest vessels and in the interstitial tissue. Local and general arteriosclerosis was found associated with various intoxications—almost uniformly in gout. Arteriosclerosis was al-

ways associated with indurative processes in the tissue and organs. It was by no means always a disease of senility, and might make its appearance at any period of life, even in childhood and infancy. It was his conviction that the disease would be recognized far more frequently in young subjects when the smaller vessels and the interstitial tissue were made the object of more careful investigation. It was probable that hereditary predisposition was a not infrequent and an important etiological factor.

Clinical Aspects.—The clinical recognition of arteriosclerosis, particularly in the young, was not always easy. The well-known accentuation of the second aortic sound was undoubtedly a pathognomonic sign when present, but its absence proved nothing. The increase of blood pressure had been shown to be by no means a constant symptom of arteriosclerosis. Hypertrophy and dilatation of the left ventricle of the heart were present in only a limited number of cases. A well-known type was that designated as cardiac. It often began in the finest branches of the coronary arteries. In the very earliest stages physical examination was practically negative, the symptoms, if any, being mainly subjective. There might possibly be a slight irregularity or a change in the rapidity of the pulse. Secondary murmurs and angina pectoris occurred later, associated with all the well-known symptoms of cardiac insufficiency. Another type might be called the renal. Here, too, the process apparently began in the interstitial renal tissue. The early stages could not be recognized clinically, even the urine ordinarily showing nothing pathological. A somewhat later stage was usually recognized by mere accident. There were still no very positive subjective symptoms, but an accidental examination of the urine, as for life insurance, would show a low specific gravity and an occasional trace of albumin with the constant presence of granular casts. Another group of arteriosclerotic cases might be described under the designation of the cerebral type. The disturbances of memory and the various forms of senile dementia had their anatomical basis undoubtedly in the arteriosclerotic condition of the brain, especially of the cortex. There were two other forms that had not been generally recognized. One of these was a spinal type, resembling in a general way the symptoms of tabes, but presenting none of the progressiveness of that disease. The other type was the gastro-intestinal, including under this head both the liver and pancreas. In many cases of arteriosclerosis the pancreas had shown an advanced state of arteriosclerosis. Possibly the glycosuria so often found in aged arteriosclerotics might be due in part to this arteriosclerosis of the pancreas.

Therapeutics.—It was quite hopeless in the present state of our knowledge to attempt to restore indurated tissues to their normal state; the most that we could hope to do was to arrest the process. This was within our power, more especially in those cases in which the arteriosclerosis was dependent upon some form of intoxication. In every case of arteriosclerosis he would urge the systematic and persistent use of the iodides. Our treatment in the main must necessarily be prophylactic, and in this connection it should be borne in mind that diet played an important part.

Dr. C. E. Quimby said that for many years he had been of the opinion that all of the processes which we call "pathic" were helpful, and were just as much a part of the biological action of the system as those which went on day by day. There was no necessity, therefore, for us to look far afield for the etiological factors. He believed that anything which affected tissue nutrition by weakening its effective forces might lead to arteriosclerosis. A process in one organ which demanded an excess of nutritive supply, and hence caused a relative diminution of the tissue supply for other parts of the body, he thought, might produce sufficient strain to result in the development of an arteriosclerosis. It was interesting in this connection to remember that very few people had all of their organs of the standard size; this meant that in almost every one the vital processes must be carried on under a condition of strain. Aortic accentuation meant only high tension for the time being, and, unless persistent, it was not an indication of arteriosclerosis. In making routine urinary examinations one should not neglect to determine the quantity, the specific gravity, and the presence or absence of casts.

Arteriosclerosis in the Young.—Dr. N. E. Brill spoke on this topic. At one time, he said, he had collected the cases of this kind that had been reported in the literature, and had himself reported a case of arteriosclerosis associated with chronic nephritis. The patient was a girl aged twelve years, who had come into the hospital in January, 1888, with a history of having been apparently perfectly well up to one week before admission, when on awakening in the morning she was found to have had an attack of hemiplegia. Two days before this she had had a headache. The heart was markedly hypertrophied, and the second aortic sound was reduplicated. The temporal arteries were tortuous and the radial arteries were hard. The urine contained a slight trace of albumin and numerous hyaline and granular casts. In a short time she had had an intense pain over the region of the spleen, probably from an infarct, and this had been followed by intestinal hemorrhage and death. The post-mortem examination had revealed as marked and diffuse an arteriosclerosis as he had ever seen in an adult. The autopsy had been made by Dr. E. Libman. The right kidney weighed 59 gm. and the left 34.5 gm. The capsules were adherent and the surface was granular.

Etiology.—The question of nicotine intoxication as a cause of arteriosclerosis he thought had not yet been demonstrated. He had been told by a prominent physician of Havana, where smoking is indulged in excessively, that among the common people arteriosclerosis was quite rare, but that it was quite common among the higher classes. This was ascribed to the fact that among the better classes the eating of large quantities of meat and the taking of little exercise were quite common. Hawkins had reported to the London Pathological Society some years ago a case of arteriosclerosis occurring in a child aged eleven years. Here there had been noted that occasionally the second aortic sound was not accentuated. This might be due to the fact that thickening of the aortic valve produced a moderate stenosis, so that a large volume of blood was not thrown into the aorta, and hence there was no sharp closure of the valve.

Arteriosclerosis in the Negro Race.—Dr. Louis Faugères Bishop said that in his experience he had found arteriosclerosis exceedingly common and well marked among the negroes. A recent case was recalled in which at autopsy the abdominal aorta had appeared like a stiff tube with only a small lumen.

Trigeminal Neuralgias.—Improve the general conditions. Apply ice or dry heat. In severe paroxysms give morphine injections. In tic give the crystalline alkaloid aconitine gr. $\frac{1}{100}$ every two hours until numbness of the tongue ensues. For continued use, morphine gr. $\frac{1}{12}$, strychnine gr. $\frac{1}{30}$ t.i.d., nitroglycerin gr. $\frac{1}{100}$. Croton chloral is often disappointing. Electricity with the positive pole to the painful area, with a galvanic current of 8 to 15 m.a. frequently gives gratifying results. Gauze wet with cocaine (twenty per cent.), chloroform, or tincture of aconite may be laid over the painful part and the negative pole of the battery applied with 12 to 20 m.a. for a few minutes.—McGregor, *The Physician and Surgeon*, January.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 7, 1901:

	Cases.	Deaths.
Tuberculosis	269	148
Typhoid fever	29	11
Scarlet fever	725	44
Measles	289	6
Diphtheria and croup	266	48
Smallpox	42	8
Varicella	54	0
Cerebro-spinal meningitis	0	3

Decreasing Birth Rate in Civilized Countries.—Referring to the downward movement as regards the birth rate in all or in most civilized countries of late years, presumably brought about by artificial means, *The British Medical Journal*, March 9th, has this to say: "It would not be wise to attempt to dogmatize on the utilitarian and ethical aspects of this modern movement (so strongly affirmed by the birth rates) in the direction of restraining reproduction. It has become established in most civilized countries and has obtained a firm foothold in Great Britain. The medical profession (with rare exceptions) has not shown any sympathy with it. The attitude toward abortion, of the medical profession as a whole, has not only been above reproach but above suspicion, and though the family doctor is not its conscience keeper, he certainly does not endorse the irresponsible voluntary limitation of the size of families. Though the French nation has practically sacrificed its prospects of future supremacy in the rivalry of races through the persistent gratification of a highly civilized individualism, the Teutonic races do not afford it a favorable soil, nor is it ever likely to become acclimatized in Great Britain."

Photographing the Stomach.—The *New York Tribune* gives the following extract from the *London Globe*: "Drs. Lange and Melzing have succeeded in taking photographs of the mucous membrane of the stomach in the living subject. A stomach tube, 66 cm. long, with a diameter of 11 mm., is introduced, having at the lower end an electric lamp and at the upper end a camera. The stomach is first emptied and washed and then distended with air. Then fifty pictures can be taken in rapid succession in from ten to fifteen minutes. By turning the apparatus on its axis all parts of the mucous membrane can be pictured. The photographs are about the size of a cherry-stone, but, of course, can be enlarged to any extent."

The State's Duty in the Prevention of Tuberculosis.—Dr. C. O. Probst, secretary of the Ohio State board of health, lays down these propositions for the prevention of tuberculosis: 1. The State should provide hospitals for the reception of consumptives, and should assist municipalities or counties to construct similar institutions. 2. Physical education, conducted by medical men, should be made a part of the common-school course; and students of colleges and universities should be instructed in hygiene, including a proper knowledge of the causes and prevention of tuberculosis. 3. The State should exercise a greater supervision over the construction, ventilation, and care of workshops and factories where the occupation is especially conducive to consumption. 4. The State should prohibit the sale of milk from tuberculous animals, and should provide for the inspection of dairy cattle. It should enforce the proper stabling and care of such animals.

Emergency Hospital for the Pan-American Exposition.—The directors of the forthcoming exposition at Buffalo appear determined to provide for the comfort of their visitors in every possible way, even to caring for them when sick or injured. With this laudable end in view, an emergency hospital has been constructed on the grounds, and, according to its description, the building must be not only eminently useful, but decidedly ornamental. It has a frontage of ninety feet; the main wing has a depth of thirty-eight feet, with a height of but one story, except in the centre, where it assumes the form of a square tower with a rounded top. This tower attains to the pretentious height of two stories, surmounted by two flagstaffs. One staff supports the exposition flag and the other the well known Red Cross banner. A rear wing, one story high, runs back from the centre portion a distance of fifty-six feet, with a width of thirty-two feet. The hospital in color is in keeping with the rest of

the exposition buildings, and resembles a low rambling adobe mission house covered with heavy red tiling. Interiorly it is fitted with all the up-to-date appliances adapted to emergency work. The first floor front contains in the extreme western wing two male wards with seven cots each, a bathroom, physicians' office, a morgue, etc. The eastern wing contains a woman's ward, large enough to hold a dozen cots. This wing also contains an office for the superintendent of nurses, private physician's office, and other conveniences. The upper story is intended for the use of the resident physician and the necessary attendants. The building is provided with natural gas for heating and cooking purposes, and water, gas, and electricity are carried to every part. Roswell Park, M.D., is the director; Vertner Kenerson, M.D., deputy director; and Dr. Alexander Allen is the resident physician. It is stated that up to March 1st, five hundred and four cases have been treated on the grounds, only one of which proved fatal. There can be no doubt that a hospital of this nature is a very necessary adjunct to an exposition, and those in charge of that at Buffalo are to be congratulated upon the erection of a structure that is not only admirably adapted to the object for which it has been built, but is also a picturesque addition to the *mis en scène*.

Some of the Properties of Oysters.—Oysters have for centuries been much esteemed by medical men as being very nutritious and easy of digestion, but both these properties are much diminished when the bivalves are not taken in their raw state. It may not be

generally known that the fluid which surrounds the oyster bears a closer analogy to the gastric secretion than anything else in nature. In addition to the solvent properties of this liquid it is not without its nutritive properties. We have of late devoted considerable attention both to the substance and the secretion emanating from it, and find that in a given weight of the latter and the same of the oyster, the fluid yields only forty per cent. less of animal gluten or jelly than the fish; consequently all persons who are accustomed to eat oysters should be ever mindful that as little as possible of the juice should be lost. To effect this purpose they should always be opened in the bottom shell. When oysters are either stewed or scalloped the two properties, as before stated, are much diminished, and consequently oysters ought not, by invalids in particular, to be taken except in their raw state.—*Sanitary Record.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 6, 1901:

		Cases.	Deaths.
Smallpox—United States and Insular.			
California, Los Angeles	March 16th to 23d	3	
San Francisco	March 16th to 23d	10	
Delaware, Seaford	March 20th	53	
District of Columbia, Washington	March 23d to 30th	8	
Florida, Jacksonville	March 23d to 30th	7	
Illinois, Chicago	March 23d to 30th	13	
Indiana, Muncie	March 1st to 31st	23	
Iowa, Clinton	March 23d to 30th	1	
Kansas, Wichita	March 23d to 30th	14	
Kentucky, Lexington	March 23d to 30th	3	
New Jersey, Jersey City	March 24th to 31st	5	
New York, New York	March 23d to 30th	41	10
Ohio, Ashtabula	March 23d to 30th	1	
Cincinnati	March 22d to 29th	4	
Cleveland	March 23d to 30th	42	1
Pennsylvania, McKeesport	March 23d to 30th	4	
Pittsburg	March 23d to 30th	2	1
Steelton	March 23d to 30th	3	
Tennessee, Memphis	March 23d to 30th	24	
Nashville	March 23d to 30th	11

Madras	February 23d to March 1st	..	1

The Etiology of Cancer.—The report of an investigating committee concluded in the July number of the *Birmingham Medical Review* contains the following: 1. Certain more or less well-defined areas exist in which the mortality from cancer is markedly above, and others in which it is markedly below, the average for England and Wales. 2. Although age and sex incidence undoubtedly influence this variation, in some cases considerably, they account for only a small proportion of it. 3. Owing to the great difficulty of diagnosis in many cases of internal cancer the death rate from cancer is probably at present underestimated. 4. Contamination of the soil or subsoil for long periods with decomposing organic matter is very probably a factor in the production of a high death rate from cancer. 5. A damp, ill-drained, water-logged soil, of whatever geological formation, is more frequently associated with a high cancer death rate than is a dry well-drained soil. 6. There is abundant evidence of the existence of groups of houses in which cancer is found with marked frequency; and some evidence which tends to show that second and third cases occur in the same house with greater frequency than can be accounted for by mere coincidence. 7. Cancer occurs more frequently in old than in new houses and districts. 8. There is some evidence suggesting that under certain circumstances cancer may possibly be transmitted from one person to another in constant close association.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE TOXÆMIA OF PREGNANCY: ITS DIAGNOSIS AND TREATMENT.[1]

BY S. MARX, M.D.,

NEW YORK.

My object in calling attention to the toxæmia of pregnancy is solely to bring to your notice a condition which is neither generally recognized nor understood. This in itself is due to manifold factors, the most important of which is the extreme complexity of the theories advanced as to the pathogenesis of the condition, or, if you please, symptom; for surely it is such, and not a disease. It is simply one manifestation of a vicious complex of symptoms showing a pernicious disturbance of metabolism. While I shall discuss in passing the various theories advanced as to its causation, it must be remembered that, the paper being merely a clinical one, the deeper problems cannot be sifted, but must be left to those of my fellows who are capable of discussing such profound biochemical subjects. I appear before you as a practitioner, not as a theorist. What we want to know is, how to diagnose and treat to a successful end the condition before us. By the toxæmia of pregnancy we mean a disturbance of the metabolism in which, simultaneously with chemical changes in the urine, there appear certain well-marked nervous symptoms, that, when not actively treated, inevitably give rise to eclamptic convulsions. I further wish to call your attention to the fact that the manifest albuminurias of pregnancy do not enter into this category, that is, not those cases dependent upon acute nephritic changes with such characteristic evidences found in the urine as albumin and casts, but it includes those cases in which the symptoms of a true nephritis are absent. In the latter cases neither albumin nor casts are present, there is nothing but a progressive diminution of the solid constituents, and our standard of measurement is the amount of urea excreted. It has always been my belief that the causal factor of the toxic state is simply the faulty excretion of urea or one of its synthetic elements. Yet the many theories of the various distinguished authors must not be ignored, since they are based upon biochemical and pathological experiments, while mine are merely the result of clinical experience at the bedside. All agree that the condition is certainly a toxæmia, but an analysis of this definition reveals as many divergent views as there are investigators in the field. In a previous paper on this subject I reviewed rapidly the various theoretical causal factors as follows: Those of the auto-infective type, as from an accumulation in the blood of a toxic material, be this urine, fæces, or both, or due to the presence of creatin or creatinin or both, or again, as has been lately advanced, a leucomain poison; or those, on the other hand, of the heterogenetic type having a bacillary origin, with bacteria toxins; or, finally —and with this view I am partially in accord—depending upon a chemical basis, as a result of anomalies of oxidation, if we may so choose to call it, as for instance, upon a carbamic-acid poisoning. Yet be the causal factor what it may, my own clinical experience has taught me that the toxæmia of pregnancy, the pre-eclamptic state, and eclampsia are conditions closely allied, and intimately wedded in one way or other, to disturbances of renal secretion. Further, that the pure toxæmia of pregnancy is always associated with kidney inadequacy, so far as the absolute diminution of secreted solid elements is concerned, and that the surest method of treatment is followed by a return of diuresis with a hypersecretion of the offending retained products. The one organic product which, in all human probability, is the most dangerous one is the chief solid constituent of the urine—namely, urea, or its congener, nitrogen. Urea in its formed state is not a very poisonous element, for large amounts have been injected into animals without bad results. And yet when approximately the same amount as is estimated to be in the blood of a woman suffering from eclampsia, is injected into similar animals, death or convulsions are the result in a short time. The toxicity of eclamptic blood or serum is more than three times stronger than that of normal blood serum. Again, on the other hand, the urine of the toxæmic state is very much less poisonous than that of the healthy gravid woman. From a clinical standpoint, I wish to place myself on record, so far as my own individual experience is concerned, that I have never seen, except once, a case in which constitutional symptoms did not arise or manifest themselves when the amount of urea excreted was normal. Toxic symptoms were always present when diminished urea excretion was noted. I was always sure that, as soon as a hypersecretion of urea could be established, there would be marked improvement in the general symptoms. The exception noted above was in a patient who had the most extreme fluctuations of urea excretion I have ever seen: one twenty-four hours, passing only 6 gm. of urea, and the next succeeding twenty-four hours, 30 to 40 gm. And yet her constitutional symptoms were a little worse from day to day, until it became necessary to induce premature labor, when all the disturbances rapidly disappeared. The only explanation of this apparent discrepancy lies in the fact that the total average for the few days she was under observation was far below the standard amount to be excreted. Consequently, there was only a relative increase, and the manifestations of a decided urea intoxication became evident. Having such evidence before me, I am satisfied that urea or its synthetic nitrogen is the sheet anchor as regards the safety of the pregnant woman, and upon its excretion, whether diminished or increased, depends the health, nay the very life of the gravid woman. I am further well satisfied that it is this very product that kills, and that quickly, and that it is nothing else, certainly not the albumin. In the typical cases of nephritis gravidarum it is not the amount of albumin that should be our index as to when to induce labor, but always the amount of urea excreted. I have on numerous occasions seen in patients large amounts of albumin in the urine and have always refrained from interfering actively so long

[1] Read before the Metropolitan Medical Society, March 20, 1901.

as a good average urea estimation could be obtained; and, on the contrary, women apparently well, exhibiting not the faintest trace of albumin, have been attacked with eclampsia as by a lightning stroke from the clear blue, in whom every measure failed to check the fatal course of the malady. A timely urea estimation might have saved the woman (and I say might, advisedly). At least, examination would have possibly given us a clew as to our line of action. A recital of the following case, a truly malignant condition, shows us the helplessness of the situation as it occasionally presents itself:

A primipara, whose past and present history was perfect up to the time of her fatal illness. She passed her seventh month of pregnancy without the slightest difficulty. The urine had been carefully examined by her husband, a physician, and another expert. This had always been normal in every respect. Just two days after the last examination she suddenly complained of a very severe headache. In eight hours, vomiting set in, which was persistent and without apparent cause. The collected urine for twelve hours—about six ounces—showed neither albumin nor casts. A urea estimation showed a diminution down to one-fourth of one per cent. She was stupid and drowsy, the pulse was rapid and small. She soon began to twitch and her condition began to be precarious. It was decided to induce labor at once. The cervix, one and one-half inches long, was intact and the os tightly closed. Hot colon irrigations were begun at once, and a preliminary cervical packing was placed to start the labor. In six hours, eclampsia appeared and I was invited to see the case. In spite of the packing introduced in the morning there was no softening of the uterine zone. I unhesitatingly advocated the performance of either a vaginal or an abdominal Cæsarean section, for nothing short of such heroic measures could possibly have saved this young woman. This was denied me by the others present, and in a few hours thereafter exitus occurred, the patient being undelivered. She had been sick hardly thirty-six hours, passing rapidly from perfect health to death in so short a time. Of course this is an extreme case, the like of which I may never encounter again, and I sincerely hope never shall; for do what you will, medical or surgical, all such patients die from an intensely acute virulent toxæmia. But, fortunately, the greatest numbers of cases respond kindly and rapidly to treatment, whether medical or surgical, provided, of course, there be a timely recognition of the persistence of a deficient urea excretion. The sooner we all realize that it is this factor, and not the amount of albumin in the urine, which should be our sole indication when and when not to induce labor, the fewer eclampsias we shall meet. In another place I made the following statement, which I do not hesitate to repeat here: "Eclampsia is as absolutely preventable as is puerperal sepsis." Nay, it is more so, since even among the best and the most careful, sepsis will occasionally creep in. Not so with eclampsia; for if men were taught, or if taught would remember, that regular examination of the urine should be made and is as essential during the whole of pregnancy as asepsis is during labor, fewer eclampsias would occur, and, ergo, fewer women and children be lost. Men depend too much upon the presence or absence of albuminuria in determining the condition of a pregnant woman. Even in the presence of constitutional symptoms, such as œdema, headache, etc., the physician rests satisfied so long as no albumin is present in the urine, and declares his patient safe; and yet, while temporizing in a position of false security, he is dealing with one of the most malignant states and fatal cases in which there is uræmia without albuminuria, a condition that can be well denominated "urinæmia" for want of a better name. As toxæmias pure and simple these cases are not so fatal; but, nevertheless, they are distinctly treacherous, because they are either not recognized at all or light dawns upon the attendant when it is too late. This, then, is my object in imparting my experience with this very grave phenomenon of the pregnant state, as well as to add another note of warning as to the timely recognition of the malady. Timely interference and intervention carry with them almost universal success. Procrastination results in inevitable death. Since it is the urea or one of its compounds that kills, and not the albumin, I wish to make a strong plea for a regular and methodical course of urea estimation in all cases, instead of the time-honored examination for albumin and casts, or at least I would relegate the latter method to secondary importance. And for the reason that urea is always found markedly diminished in these so-called true toxæmias or, if you choose, urinæmias of pregnancy, our only true guide and indication for active interference is never the amount of albumin present. Only when in the face of active medical treatment there still persists a progressive diminution of the total amount of urea excreted in twenty-four hours do I advise surgical intervention. As to the diagnosis, when these facts pertaining to the urine are kept in one's mind there should be no difficulty. But the great trouble with many observers is that such a condition never dawns upon them, since they have been taught, and they themselves will teach, that the uræmic state is always associated with casts and albumin in large amounts. This reasoning and teaching are not only absolutely wrong but positively dangerous. Have we not all seen women go to term with positive evidence of grave nephritic disease, with little or no discomfort? And, on the other hand, I have personally seen at least ten cases perish without the slightest evidences of either albumin or casts in the urine. Among these I number two women the wives of colleagues, who died, I am ashamed to say, solely for the reason that their husbands were doctors. Are not all our own wives open, possibly, to this same neglect? I say positively yes, because I know whereof I talk—from bitter experience. The estimation of the amount of urea must always, if possible, be obtained from the total twenty-four-hour urine. The urine as a rule is diminished in amount, but not always, since in one case, that of a physician's wife, sixty ounces were passed in twenty-four hours. The specific gravity is generally low, and chemical examination shows no albumin or but a trace. Microscopy reveals little or nothing, an occasional hyaline cast being perhaps found after a lengthy search. But positively characteristic and always found is a marked diminution of the total amount of urea excretion. Instead of being the usual average, 0.02 in 1 c.c., I have repeatedly noted from 0.005 down to 0.001. Peculiarly enough, there are very often present larger or smaller amounts of sugar, but whether this shows a possible involvement of the liver in the toxæmia or is the cause of the latter, I am unable to say. It must nevertheless be remembered that glycosuria is of very frequent occurrence in the pregnant state. It is only after a very severe convulsion or after the uterus is emptied that both albumin and casts are found in the urine in the great majority of cases.

As regards the symptoms, they are generally those of a systemic intoxication. In rare cases they appear with lightning rapidity, without premonition. In most cases, on account of the insidious absorption of the excretory elements, there is noted a very gradual systemic intoxication. So gradually are the symptoms developed that they escape attention, yet they are sufficient for the careful observer to determine that a toxæmia is present. Patients so affected complain of a severe headache which persists and increases in spite

of all measures. It is not localized, but spreads all over the top of the head and down into the nape of the neck. There are nausea and vomiting but not those of pregnancy, since they occur at all times and are preceded by that peculiar feeling of goneness, emptiness, or painful faint feelings in the pit of the stomach. The vomiting may be so severe as to become almost uncontrollable. The presence of œdema is characteristic. It is erratic. At times the patient is bloated to a marked degree, and then in a few hours the œdema will have entirely disappeared. Again, there are temporary local œdemas, such as on one hand or foot, disappearing as quickly as they arise. It is this peculiar fugitive symptom which is as typical as any, and, to my mind, characteristic of this condition. Convulsions before labor are very rare; but when they occur they are preceded for days by twitchings which are limited to the face or to one or the other of the extremities. The explosion occurs often during or immediately after labor. This is followed by an increased discharge of urine. With this comes an increased excretion of urea, and with it albumin and casts appear for the first time. The albumin gradually increases, and then slowly diminishes in proportion as the urea increases. It would not be amiss at this time to narrate in a few words two typical cases. In one, by timely treatment I was able absolutely to overcome the toxæmia and carry the woman on to term when she was delivered normally, without the least trouble; while in the other case, because the diagnosis had not been made and a number of other measures instituted for various diagnoses, I was compelled strongly to advise the interruption of the pregnancy as soon as the diagnosis had been verified by a urea estimation.

G. H——, multipara. At the third month of pregnancy, having been previously well, she began to complain of gradually increasing headaches. These rapidly increased in severity and were soon accompanied by attacks of dizziness. Soon she was unable to see well and complained of spots before the eyes. She noticed that she was passing less urine. She was attended by her physician, who found nothing the matter with the urine as to casts or albumin. She was passing about twenty ounces of urine, and on making a urea estimation he found that she was excreting but 12 gm. of urea in twenty-four hours. Upon my advice she was put to bed, all the emunctories were stimulated, milk diet was given, and glonoin gr. $\frac{1}{50}$ four times daily ordered. From the very start the condition steadily improved and all the symptoms disappeared. As the chart indicates, the amount of urine rose at once, with an increased amount of urea:

First	day—Urea,	250	grains	in	84	ounces	of	urine.
Second	"	"	280	"	"	92	"	"	"
Third	"	"	300	"	"	96	"	"	"
Fourth	"	"	380	"	"	98	"	"	"

At this time she had practically lost all her symptoms, when her child was taken ill and died. She was compelled to neglect herself and she rapidly went back to her old condition. The dizziness and headaches appeared again. Urinary examination showed a diminished amount of urea, but the urine was passed in large amounts.

First	week—Urea,	170	grains	in	110	ounces	of	urine.
Second	"	"	380	"	"	152	"	"	"
Third	"	"	400	"	"	176	"	"	"

Her symptoms again rapidly disappeared under treatment and remained away permanently, and she was delivered at term in a normal fashion.

The second case to be related was in the wife of a physician. She had always been in good health and was at the time in the third month of her second pregnancy. For the previous six weeks she had suffered from very severe and increasing headaches, which were unbearable at night. She had the usual nausea and vomiting of pregnancy. She felt rather weak and was becoming more and more anæmic. She was considerably annoyed by varicosities in the vagina, vulva, and upper part of the thighs, apparently increasing from day to day. Occasionally the arm and face were swollen, but this condition passed away very quickly. She was in charge of another physician when I was asked to see her. She was passing but twenty-one ounces of urine, and on examination of the collected twenty-four-hour specimens no albumin was found, the chlorides were markedly diminished, and under the microscope no formed elements were found. A urea estimation revealed but 0.015 per 1 c.c.; consequently, she was excreting but 9 + gm. in twenty-four hours, instead of 30 gm., which is the normal average. She was put to bed, under active treatment, but the condition did not improve; on the contrary, the headaches became very much worse. In thirty-six hours the urea in the twenty-four hours fell to 6 gm. in spite of very active treatment. The induction of an abortion was advised and rapidly done, and the patient made a speedy recovery. The symptoms, especially the headaches, quickly disappeared. Examination of the urine one week later showed large amounts of phosphates, and the chlorides very much increased; a very distinct ring of albumin was found with nitric acid. The microscope revealed a few suspicious formed elements, probably destroyed renal casts. The amount of urea in 1 c.c. of the collected urine was 0.02, which was approximately normal. At present, more than a year later, the patient is perfectly well and in robust health.

Treatment: In speaking of the treatment of this condition I must first refer to the prophylactic measures. It is within the province of every practitioner of midwifery to surround his patient with each and every precaution which would, or at least should, minimize the dangers during the pregnant state, and consequently lessen the possibilities of untoward complications during the puerperium. The most important measure is the regular examination of the urine, not in a perfunctory fashion as to albumin and casts, but for a methodical estimation, at weekly or semimonthly intervals, for the amount of urea excreted in a given twenty-four hours. Such an estimation is as quickly made as an ordinary urinary examination. It has been my custom for some time to depend upon such urea estimations primarily, and subsidiarily to this the albumin and cast investigation guide me in gauging the condition of my patient's health. In other words, albumin and casts have no meaning for me in the presence of a normal urea excretion, for with that I am in a position to know that sufficient of the effete products are being excreted and the condition of my safety valve in the engine of the body is evidenced by the behavior of this element. This is my sole guide, for I know of no better index of the workings of the great inner and practically unknown physiological machine. Whether this urea is really the offending agent or not, modern investigation does not allow us to state with any degree of positiveness. It is enough to this end to state that when there is a lessened secretion the patient suffers, and when hypersecretion occurs the patient is freed from those symptoms indicative of toxæmia. Successfully to treat these patients there must be absolute rest in bed. Every emunctory must be stimulated by means of drugs having specific action on the various excretory channels—the bowels by calomel, jalap, elaterium, or the various salines; the skin by hot packs, sweatings, or the milder diaphoretics. As to pilocarpine, I am opposed to it, for while it is a certain and powerful diaphoretic, it acts at the expense of the other secretions. It is a drug not devoid of danger, and for this reason I am opposed to its use. Of prime importance are those measures instituted directly to influence uri-

nary secretion. If I should appear to be dogmatic in what follows concerning my lines of treatment, I certainly wish to disclaim any intention to be so. I simply give the result to you for what it is worth, after years of experience in seeing and treating many toxæmic cases. I simply quote what I stated at another time in 1896.

Diet: Milk, buttermilk, kumyss, matzoon. Water is given in large amounts to flush the kidneys; my preference being a mild saline or pure spring water. Of the greatest value are hot rectal or colon injections, quarts at a time being given with the patient on her side, with the buttocks elevated. These act exceedingly well not only as a food, but as direct urinary stimulants.

Drugs: There are many to choose from. The refrigerant diuretics of the sodium class (potassium salts are all too depressant) with an infusion of buchu or triticum stand well in my estimation. Digitalis is the drug which seems to be the sheet anchor for most physicians. But in toxæmia, to my mind, it is positively contraindicated, since digitalis, possibly because of its digitoxin, is a decided and direct renal irritant and has no place in the treatment of a condition in which there is present at least a functional irregularity of the kidney. Among the drugs of unquestioned value are the vasodilators, and first and foremost nitroglycerin, nitrite of sodium, chloral, and small doses of opium. Among the true heart tonics are sparteine and the caffeine salts, either pure or in one of the usual double combinations which are soluble and given in double the amount. Strychnine I reserve for those cases in which there is a low-tension pulse, and in this condition it is a very valuable remedy. I have little to say in praise of veratrum viride. Unquestionably it will reduce both the volume and rapidity of the pulse; but of what value is such a reduction when it is symptomatic and not curative? The statement has often been made that when under its influence the pulse becomes soft, slow, and compressible, convulsions do not occur. I wish to deny this emphatically and in unmeasured terms, since I have seen awful convulsions when the pulse was 60 and alarmingly feeble. In a fatal case, that of the wife of a physician, a convulsion occurred one-half hour after an induced labor. The pulse was full and bounding and 178 to the minute. Hypodermics of full doses of veratrum viride sent the pulse down to 60, when it was hardly to be felt, and yet the worst convulsion the patient ever had occurred at this time and she succumbed to the malady in a short time. And yet in another woman full doses of a reliable preparation were given to control the fits while the pulse was full and bounding and the face deeply cyanotic, and neither the pulse nor the very severe convulsions were controlled. These and other cases, the results in which were entirely unsatisfactory, make me a sceptic as to the real curative value of this drug; and while I do not doubt that physiologically the drug will achieve its end, yet what we are after is not this—a symptomatic cure restricted to one symptom—but a clinical and complete cure.

Now, finally, as to venesection as pertains to its performance before the uterus is emptied. As in the use of veratrum so with bleeding: when there is an indication for either, there is also an indication for promptly emptying the uterus. If, then, after the uterus is emptied there is an indication for the abstraction of blood, let it be from that organ; take no measure to insure firm contraction of that viscus, but allow a free and copious hemorrhage to take place until the pulse becomes soft, feeble, and slow. I am an absolute and firm believer in the abstraction of blood when fully indicated in the cases of women in whom we find a high-tension, rapid pulse, deeply congested and cyanotic face, and threatened or already present convulsions. Whether this abstraction is from the arm or from the uterus, by leeches or wet cupping, is very immaterial so long as we bleed and bleed sufficiently to relieve the intense cyanosis and make the pulse soft and feeble. One of the most desperate cases I ever saw occurred in a young primipara, who suffered from an intense toxæmia before labor. She was delivered spontaneously of a dead child at the eighth month. Her condition did not improve after delivery, and in twenty-four hours she developed one convulsion after the other, four in the first hour, and soon became absolutely unconscious, with a pulse of 160 and tension very high. In spite of all measures her condition became rapidly worse. The fluid extract of veratrum was repeatedly injected, ℥x. at a time, but to no avail; the pulse ran up to 180, with tension greater than I had ever seen, and deepening coma—in fact, she presented the picture of a dying woman. As a forlorn hope I cut into the elbow veins. Sharp venous spouting occurred, so intense was the congestion, and in ten minutes—the time it took to abstract about one pint of blood—the pulse had fallen to 80 and was soft and feeble, the countenance of the patient was one of quiet repose, and she became semiconscious. The same condition, except the coma, returned in twelve hours; when, as she refused to allow the use of the scalpel, I applied sixteen leeches to various parts of the body and in twenty minutes all her symptoms had disappeared, and from this time on she made a complete recovery.

The lines of treatment advocated above are purely medical and are advanced from a tentative standpoint. In using them I am ever hopeful that the tide may turn at any moment for the better. And yet it is a principle with me to operate rather too early than too late; surgical measures are to be instituted at once when medical means have failed us. And when is this? It is a firm dogma with me that when, after a short time of active conscientious treatment, the urea estimation (above all clinical facts) shows no improvement—and certainly always when the excretion decreases progressively—to empty the uterus at once by any method which attains this end most quickly, safely, and surely. After labor the danger of convulsions is very remote, since in only five per cent. of the cases are they likely to occur. Should they nevertheless take place, a profuse abstraction of blood in the appropriate cases will give excellent results. Chloral in large doses and chloroform by inhalation are indicated, to ward off the attacks and to allay the seizures. Full doses of codeine, gr. ii.–iv. per rectum, have been a useful measure in my hands. And, finally, I stimulate the emunctories by all means, depending especially upon the use of continuous hot colonic irrigations of a salt solution. These, then, are the measures at my command, which I can recommend. Should I have fallen short of your expectations I have done so probably because you have been expecting something novel and startling. If such, then, were your anticipations, you must remember that the problem I was called upon to present to you has been the nightmare of scientists for many years, and is still to this day the moot and abstruse problem it ever has been. But if I should have impressed upon your minds only the following conclusions, then, and then only, would I feel that my weak efforts have not been in vain.[1]

1. Toxæmia of pregnancy is a complex condition depending on more than one factor.

2. Many women go to term with albuminuria, without symptoms referable to a toxæmia. When such symptoms arise they are not caused by the albumin present, but by faulty urea secretion.

3. In the most desperate and malignant cases there is found neither albumin nor casts.

[1] Medical News, June 30, 1900.

4. Urea is always found markedly diminished in the so-called true toxæmias of pregnancy, or urinæmias.

5. Finally, I make a strong plea for a regular and methodical course of urea estimation in all cases of toxæmia, or for the relegation to secondary importance of the time-honored examination for albumin.

6. Progressive diminution of urea excretion, with or without albuminuria, is the sole indication for the induction of premature labor, which is especially indicated when conscientious medical treatment fails.

947 Madison Avenue.

FAITH CURES AND THE LAW.

By JOHN B. HUBER, M.D.,

NEW YORK.

On a day in February last I was at one of three hearings in the assembly chamber at Albany, upon the bill introduced by Mr. Bell, to the end that irregular practitioners should be compelled to take examinations after the manner required of those who become registered physicians. In essence this bill simply aims to compel those who would treat the sick to evidence an adequate knowledge of the structure of the human body and of the processes by which life is maintained, and to demonstrate their ability to differentiate one disease from another; in short, to satisfy what I understand to be a legal requirement, that "a person undertaking any duty must possess skill and knowledge competent for its successful discharge."

Representatives of various peculiar movements were present in great numbers to oppose this bill. The committee room, in which such hearings are usually held, was hopelessly inadequate to accommodate them, and they filled the assembly chamber. Among them were very few men. Especially conspicuous were those who go by the grotesque misnomer of Christian scientists.

These latter base their claims as "healers" upon their absolute denial of the existence of the human body; nay, more, they are proud of, and vaunt their complete repudiation of, the most fundamental facts of life. All diseases are alike to them in being non-existent—a cancer as well as a headache; typhoid fever as well as dyspepsia; a broken leg as well as a nasal catarrh; a case of diphtheria or smallpox as well as one of hives. All alike they would treat in but one way—by meditating and talking and doing absolutely nothing else.

Let us note some of the discussion which took place at this hearing.

One Mr. Richardson, who appeared for an organization called the State Association of Spiritualists, began his address with the statement that clairvoyance was now generally recognized as a well-established principle. "There are clairvoyants," said he, "who can see and describe persons at a great distance; and if they can do this, is it not reasonable to suppose that they can see the internal workings of the human system?" Mr. Richardson answered his own question by saying that it was not only reasonable, but it was certain that clairvoyants could do this. Not only this; they could also diagnose disease and tell the remedies that were to be used. When asked by an assemblyman how people came by this wonderful faculty, he answered, "It is a gift."

Mr. Kinter, a Christian-science healer from Buffalo, was asked if the training Christian scientists received gave them the ability to diagnose disease. "Yes, sir, it does," answered he; "I myself have treated thousands of cases. Isn't it fair to suppose that I know something about diagnosing disease?"

"Then let me ask you a question, which you can answer simply yes or no," said a physician who was present. "Would your treatment in the case of a cerebral abscess, a fracture of a bone, a hemorrhage of an artery, or a case of smallpox differ?"

"No, sir, it would not," answered Mr. Kinter.

"Well, then, if your treatment never differs," asked an assemblyman, "what is the necessity for your making a diagnosis?"

"Really, there is none, sir." answered Mr. Kinter.

Mr. Carol Norton, a Christian-science lecturer, was asked, "Do you treat animals and plants?"

"To the extent that there is mind back of animal life, we can."

"Suppose a cow were sick, would you treat her by your method?"

"Yes."

"Suppose a child swallowed a fishbone; what would you do in such a case?"

"I have treated similar cases to that, in which I have caused, merely by prayer, a relaxation of the muscles, which allowed the child to cough up the bone."

Asked what he would do in the event of a person cutting an artery, Mr. Norton replied:

"I would put a piece of plaster on it to prevent the dirt from getting in, and then would use my mind to stop inflammation or poisoning. Why, by the use of my mind I have been able to stop an unusual flow of blood in an instant. This bleeding to death only exists in your mind."

Mr. Norton went on to explain that in sickness it was necessary for the patient not to use his own mind, but to use his (Norton's) mind. He recited an instance of a boy having gone down in the water for the third time, being under the water for fifteen minutes, and having been laid on the dock apparently dead. Mr. Norton just went to work with his mental treatment and did not use any of the agencies generally employed in resuscitating drowning persons, and after a half-hour of such mental treatment the boy came to life and began to throw the water off his stomach, without having been rolled over a barrel or subjected to such other devices common to ordinary minds.

While the hearing went on I contemplated the great number of enthusiasts who had come into this magnificent chamber to impress the assembly committee and to uphold their leaders. The opportunity to study hysteria was one the like of which I shall probably never again realize. I vividly recalled Poe's story of how he had inadvertently happened into a *maison de santé;* and I could quite appreciate the observation of a colleague that the situation made him think of nothing in the world so much as of one of Charcot's clinics on an enlarged scale.

One would suppose now, at the beginning of the twentieth century, when men generally think sanely and reasonably, when we have come to substitute for superstition the habit of accounting for physical manifestations upon scientific bases, when science has made evident the value of sanitation, hygiene, and clean living in inducing happiness and well-being and in dispelling disease, that these peculiar movements would be impossible. As a matter of fact, it is difficult to conceive how they could ever have been more numerous than they are nowadays. A great many of them have emanated from or near Boston, a region resourceful in the production of cults which have for their basic principle dissatisfaction with the universal scheme. Such movements are to be looked upon, it seems to me, as epidemic psychoses. They resemble in all essentials the innumerable epidemics of abnormal mentality which have been born, have lived, and have died during the centuries. Whatever differences there may be, are of degree rather than of kind. The following are the main elements which make for

their success: First, the activity of a leader who is either unscrupulous or of abnormal mentality, or both. Then there is the assumption of religion. Eddyism and like hypocrisies attract very many honest and devout people who are under the impression that these movements must be good and wholesome because they invite adherence in the name of religion. Other essential features in these epidemics are the influence of imitation, suggestion, and the contagion inherent in social excitements.

To the student of human kind there can be no more interesting study than that of such cults as these. The works of Le Bon, Podmore, Jastrow, Patrick, and others are most inviting. They read like novels—infinitely more so than many of those which inundate us nowadays. I take from Le Bon's book, "The Crowd: a Study of the Popular Mind," this suggestive sentence: "The quality of the individual in the crowd is without importance. From the moment they are in the crowd the ignorant and the learned are equally incapable of observation." From the perusal of such works as these we may comprehend the spread of many extraordinary movements in times other than our own, viz.: the crusades instigated by Peter the Hermit; the children's crusades; the dancing manias of the Middle Ages; the witch persecutions; the tulip mania in Holland; the French Revolution; epidemic religious revivals in all countries, notably those in America in the time of the elder Edwards; the South Sea bubble, the Mississippi scheme, and the countless like phenomena with which the pages of history teem.

And the reader of these works will then understand, I believe, how it has come to pass in our day that a Simpson can relieve his packed audiences of their millions, how a Sanford or a Dowie can degrade the multitudes subject to their baneful influence, how a "Truth" can gull his thousands, and how Eddyism has come to be the most pernicious and the most prodigious social and religious falsehood of our generation.

There are, indeed, literally hundreds of pernicious movements which are in these times infecting the national life. There is time for me to mention only a few among them.

Besides Christian science, the movement called osteopathy just now is rather rife. It has been originated by one so-called "Dr. Still" of Missouri. According to Still, all diseases are due to some deformity or displacement of one or more bones of the body. The following statement in a pamphlet which I have received, is by far the truest which it contains: "Take the average man of to-day, go through the whole category of subjects with which he is brought into daily contact, and you will find nothing with which he is so deplorably ignorant as with his own body." "Not so with the osteopath," goes on the pamphlet, "he must know his anatomy and physiology perfectly, and must understand thoroughly the chemistry of the human body." Then why do these people fear examinations, as required by the Bell bill, as a tramp does water? Probably not a single one among the whole crew could pass a decent examination in these subjects. They have bitterly contended in various legislatures, as they are now contending in Albany, against the passage of laws framed to compel them to take State examinations in such subjects, although they pretend to know them with knowledge transcendent. Cure by osteopathy of any disease—cancer, typhoid, diphtheria, consumption, no matter what it is—consists in correcting the condition or the position of an offending bone. It is generally one of the vertebræ which is the culprit. This requires a long course of treatment "by massage." Most absurd all this—and infinitely worse than absurd. Nevertheless, we find these people importuning our legislatures, and, in some instances, actually receiving special legislative license. They lately bade fair to achieve such a result in this Empire State of ours.

Experience has taught me not to hope to review the pamphlet from which I take these statements, without coming upon attempts to make sacred literature influential in behalf of this system. "Much good," it is stated, "can come out of Missouri as well as Nazareth." "God speed the day when the Science shall be better known." The following falsehood is characteristic of pamphlets of this sort: "The science of osteopathy is recognized by the most intelligent of our land, and some of the most learned of the medical profession have seen fit to adopt its principles and practice."

I mention now the names only of Mrs. Henry Milmans, one among the many who have abjured Christian science, and who now conduct enterprises of their own; the so-called "Reverend" Charles F. McLean and many others who have claimed to be Francis Schlatter come to life again; the Fire-Baptized Holiness Association; the Peculiar People; the Holiness Society, of West Virginia; the cure in Maryland, by "saying words"; the Pennsylvania Hexen Charms; the Metaphysical Healers; the Mind Curists; the Viticulturists; the Magnetic Healers; the Phrenopathists; the Sun-curists; the medical clairvoyants; the Esoteric Vibrationists; the Occultists; the Venopathists; the Psychic Scientists; those who furnish astrological health guides; those who use or abuse the manipulations of hypnotism; those who claim the power to concentrate the magnetism of the air and to excite the vital fluids "by arousing the proper mental vibrations," or by some equally lucid and demonstrable procedure; those who advertise magnetic cups and positive and negative powders; those who treat absently by outputs of psychic force; "Colleges of Fine Forces" and "Psychic Research Companies," which offer diplomas and degrees for a three-weeks' course of study or the reading of a book; etc., practically without limit.

I shall devote the rest of my paper to Christian science, or Eddyism. This cult is worthy of special consideration as being, I think, fairly typical of these movements.

Its baneful characteristics are now matters of general knowledge. I shall confine myself to two of its aspects; namely, the claims of its "healers" and its pseudo-religious character.

The system of medicine which is taught in the great medical colleges of to-day is an epitome of the accumulated study and experience of mankind from the time human beings first became ill up to the present day. All systems of cure, or of alleged cure, have been examined by men who have made it the work of their lives to treat the sick. Whatever has been found curative has been retained, and unsubstantiated claims to cure have been discarded. So that the regular degree of doctor of medicine accredits its recipient with an adequate knowledge of the system of treating disease which is a crystallization of the world's best medical thought, study, and experience.

As the possessor of such a degree, I spent several months in an investigation of the cures which Christian-science "healers" were said to have accomplished. I beg now to submit the results of my study.

After a great deal of labor and after questioning a great many persons, I was able to get together the medical histories of twenty people who considered that they had been "healed in Christian science." These cases were offered me by their leaders. They were looked upon as remarkable cures. The failures I had no opportunity to examine. What was remarkable to me was the vast disproportion between the claims of these "healers" and the results of my investigation.

My findings (in which the cases were numbered,

but not named) were set forth in a serial paper in the New York *Medical News*, beginning with January 23, 1899; and they were epitomized in a paper in the New York *Popular Science Monthly*, of October, 1899. And I have yet to come upon any disputation of the statements made in these papers.

To be specific: I had heard of patients with yellow fever, locomotor ataxia, cancer, and phthisis, that were well and happy after having gone through fearful ordeals at the hands of ordinary physicians; these cases I was not permitted to examine. Mrs. Eddy has stated: "I healed consumption in its last stages, the lungs being mostly consumed." "I healed carious bones which could be dented with the finger; I healed them while the doctors were preparing their instruments for operation." "I healed in one visit a cancer that had so eaten the flesh of the neck as to expose the jugular vein so that it stood out like a cord." Judge Septimus J. Hanna, Mrs. Eddy's counsel, has issued a statement to the effect that "cancer, malignant tumor, consumption, broken bones, and broken tissues, in numerous instances had been healed through the power of Christian-science prayer, without the assistance of any material means whatever." Mr. Carol Norton has publicly announced that Christian science has cured "locomotor ataxia, skin and bone diseases, palsy, softening of the brain, paresis, consumption, tumor, Bright's disease," etc. Judge William D. Ewing has publicly stated that "under the power of Christian science the lame do walk, and the blind do see."

I did not in my investigation come upon a single case of these diseases which I have enumerated. Not one—from yellow fever down to blindness.

Investigators have for years been asking who these people are that have thus been cured, what their names are, where they live, how they can be found, and if Mrs. Eddy and her associates will submit such cases for scientific examination. Concerning such data as these we are as well informed as we are of the contents of the Sibylline Books. We must presume from their titles that Judge Hanna and Judge Ewing are or have been judges. Imagine either of these gentlemen on the bench; and imagine him accepting as evidence these uncorroborated and unsubstantiated allegations made by Mrs. Eddy and her associates. With what more or less suppressed mirth would the lawyers present, down to the most recent graduate, greet such ruling! How rapidly would the outraged counsel in the case appeal to higher and saner courts! With what despatch would the disgraced community attend to the impeachment of such a judge!

Most of the Christian-science "cases" I came upon were hysterics. Every physician knows that untruthfulness is a characteristic of such sufferers. Whether in a given case the untruthfulness is a subjective symptom of the disease, or whether it is inherently temperamental, we need not speculate. Suffice it to say that the uncorroborated testimony of a hysteric, from a scientific point of view, and as evidence, is not worth the breath required for its utterance.

As to the religious pretensions of Christian science! Let us presume for the moment that these pretensions are well founded. It is declared that this is a religious system; that the treatment of the sick is a part of this system, and that, as the Constitution forbids interference by the States with religion, no laws can be enacted which could compel the healer to desist from his work. But I ask the gentlemen of the law who are present if there is not a sharp distinction between religious liberty and license to commit in the name of religion unlawful acts. Surely a man would not be justified in killing his child in obedience to a fanatical belief, as Abraham was about to do. But Christian science has sacrificed the lives of many little children upon the altar of its pseudo-religion. Had not these children rights which ought to have been safeguarded? If the Christian scientists' position be admitted, a thug might, I submit, upon the same principle, be justified in committing murder, on the ground that murder is a practice required by his religion; and a Mormon might, on the same basis, practise polygamy. And when a "healer" treats for hire a sufferer from typhoid fever, is he acting in a religious capacity? And when a person, ignorant of the most rudimentary principles of sanitary science, treats those who are sick of contagious disease, in wilful disregard of laws enacted to conserve the general health of the community, may he claim respect for his personal liberty, to the jeopardy of the lives of his reasonable and sane neighbors? But from my study I derive the opinion that the assumption of religious motives by Mrs. Eddy and her associates is as false as can possibly be conceived.

If they really have the good of human kind at heart, they are certainly the oddest and the most original truth-holders and truth-offenders that have ever appeared in the world's history. The chiefest and the one essential attribute of those who have tried to help their fellows has been absolute unselfishness. And the greatest among these, the most mankind-loving of them all, He in whose name these people assume to speak, was of all the most self-abnegating. "Ye are my witness," said he to his followers. Let us see what manner of witnesses these are.

Mrs. Eddy declares that "no human being or agency taught me the truths of Christian science, and no human agency can overthrow it." However, there are published statements, of the truth of which the writers offer to give legal proof, in which it is shown, by means of the deadly parallel, that the essential ideas underlying her system are all plagiarized from the writings of one Dr. Quimby, an irregular practitioner to whom, many years ago, she went for treatment. Published accounts of her illness at that time present a picture of hysteria pure and simple.

In 1881, some time after Dr. Quimby's death, Mrs. Eddy established her metaphysical college in Boston. Her fees for tuition here were $300 for a two-weeks' course. Much of her teaching has been most pernicious and repellent; for instance, her declaration that she is able to reproduce in one of her own sex the miracle recorded of the Virgin Mary. There is much else that is unsavory. But what is here set down is no doubt sufficiently indicative.

Mrs. Eddy despises all metaphysical systems, yet her writings display her inability to think logically through half a dozen consecutive lines. She claims to possess healing powers nothing short of miraculous; yet it is declared that she has probably not been a well woman these forty years past. The New York *Evening Post* stated some time ago that she is now ill with cancer. Certain it is she never appears in public, and only a few of her followers have ever seen her face, except in copyrighted photographs.

Mrs. Eddy's desecrating hand has spared not even the Lord's Prayer, probably the most perfect prayer that has ever been made, for she has tainted it with such amendments as these: "Our Father, *Mother* God, all adorable, harmonious in One." And throughout her desecration is interspersed jargon from her book "Science and Health."

She has, with unspeakable presumption, pretended to imitate the healings ascribed to the Master; but, in a spirit woefully unlike His, has profited greatly by the exhibition of her alleged power.

Many of her followers are unquestionably good and worthy people. These demonstrate anew the hoary and fundamental fact that mankind, in large proportion, evinces a burning eagerness to be gulled. And it is evident that Mrs. Eddy and her associates fully

understand, and know well, how to reap the utmost advantage from this trait in human nature.

The disjointed data which I here set down merely suggest factors in the immense, shrewdly managed organization for the extraction of wealth from the pockets of the weak-minded, which Mrs. Eddy has founded. And her propaganda has made her conspicuously rich even in these days of enormous fortunes. And this woman would stand by the side of, nay, be superior to, the poor Nazarene.

Most Christian scientists are well-to-do. In the borough of Manhattan there are four churches, all in the neighborhood of the wealthy; and two new churches of truly magnificent proportions are now building. There are no missions by which the professed blessings of Christian science may be disseminated among the poor; and there are no dispensaries in which the poor may receive Christian-science "treatment."

"No one has any business to be poor," is a tenet in Christian science. The leaders of all these churches in Manhattan borough are women, one of whom, at least, enters the pulpit gowned and bediamonded as for a social function.

These leaders, as I understand it, have received their Christian-science education directly from Mrs. Eddy. What they have learned they disseminate to others in classes. There are two classes a year, in each of which thirty students are taught how they may in their turn reap the profits to be got out of Christian science. The class lasts three weeks, and the student pays $100. The leader then realizes from this source alone $6,000 a year, an amount merely accessory to the income she receives from her church position and from the exhibition of her alleged healing powers; for it is a principle redundantly enunciated that "it costs to be healed in Christian science."

Such is the spirit dominating this cult. What would He say and do were he among them, who with righteous indignation scourged the money-lenders in the temple?

In brief, the observer will find in Christian science much charlatanry (by which many honest fanatics are deceived), much to surprise reason and common sense, to offend good taste and the proprieties, to outrage justice and the law, and to mortify the pious.

And in the last degree reprehensible will appear this cult's ghastly masquerade in the garb of Him that prayed in the Garden of Gethsemane, "the pale, staggering Jew, with the crown of thorns upon his bleeding head," the tenderest, the divinest, the most mankind-loving personality the world has ever known.

41 West Forty-fifth Street.

A New Treatment for Tuberculosis.—For the past two and a-half years, O. A. Fliesburg has used the following formula: ℞ Iodi puri cryst., 1.50; phosphori puri, 0.25; thymolis, mentholis, āā 2.50; guaiacolis, 1.25; ol. morrhuæ sterilisat., 50.00. Ft. sol. secundum artem. Sig.: Use only hypodermically. For tuberculosis of the lungs, throat, glands, and intestines, one to three syringefuls once a day, preferably in the forenoon; for tuberculosis of joints and tendons inject into foci deeply, and then apply bandage; repeat in four to eight days as necessary. The injection, if made deeply into the muscles, is not painful, and causes hardly any erythema or induration. If these occur at all, they always disappear in from forty-eight to seventy-two hours, without suppuration. There is sometimes at the beginning of treatment a slight fever of one or two degrees F. The injections should never be made in the same place twice in succession.—*Northwestern Lancet*, March 15, 1901.

REPORT OF THREE CASES OF MALIGNANT ENDOCARDITIS: ONE FOLLOWING MEASLES, ANOTHER TYPHOID FEVER IN A CHILD AND SIMULATING SPLENIC-LYMPHATIC LEUKÆMIA, AND ANOTHER TERMINATING IN RECOVERY.

By ALBERT E. ROUSSEL, M.D.,

Philadelphia, Pa.,

Adjunct Professor of Practice and of Clinical Medicine, Medico-Chirurgical College; Consulting Physician to the Hayes Mechanics' Home and to the Temporary Home; Visiting Physician to the Howard Hospital, etc.

Case I.—M. O——, female, single, aged twenty-two years, white, American, was admitted into the Howard Hospital, November 21, 1899. The following history was subsequently obtained from the family: The patient had been a remarkably healthy girl, and had experienced only an attack of mumps at the age of six years and occasional attacks of mild bronchitis. She had attended school until eighteen years of age, and subsequent to that time had helped her mother with the household duties and the care of three younger children. Three evenings during the week she assisted her father in taking charge of the books of a beneficial organization. On or about October 25th the youngest child, and shortly afterward the two others, developed attacks of measles and were nursed by our patient, who in turn contracted the disease at about the time of the convalescence of the children. The malady passed through an apparently regular course, but notwithstanding the remonstrance of the attending physician she insisted on continuing to look after her brother and two sisters. However, convalescence was apparently well established when, about November 8th, the patient was seized with a decided chill, followed by a high fever and pains throughout the body. After the first few days she lost strength rapidly, was delirious at night, and complained of oppression in breathing. During this time she was treated for supposed typhoid fever.

I saw the patient within a few hours after her admission to the hospital, and found her evidently a very ill woman. The temperature at this time was 103.8° F.; respiration, 36; pulse, 128, small in volume, and compressible. Her expression was dull and listless; her tongue was dry and thickly coated with white fur. Examination of the chest revealed a few small and large moist râles scattered over a wide area; the lungs were normal. The apex beat of the heart was in the fifth interspace in the nipple line, the impulse was feeble and diffuse, yet tumultuous in action. On auscultation a distinct, rather low-pitched murmur was heard at the apex and was transmitted into the axilla. The area of dulness was apparently not increased. The spleen was enlarged about two fingers' breadth below the costal margin. The liver also was enlarged, but not to any great extent. There were no tenderness over the right iliac fossa, no tympanites, and no spots. The bowels had been constipated.

November 22d, 7 A.M., T., 104°; P., 120; R., 36. 1:45 P.M., T., 104.8°; P., 128; R., 36. 10 P.M., T., 106.4°; P., 158; R., 48.

The urinary examination, inclusive of diazo reaction, was negative. The blood did not respond to the Widal test. Red corpuscles, 3,970,000; white corpuscles, 14,000; hæmoglobin, 40 per cent. The patient at the time of my visit (1:45 P.M.) was losing ground rapidly. The body was covered with cold sweat. The heart murmur was still heard, but the action was weak and irregular. Malignant endocarditis was mentioned to the interne as the probable diagnosis.

November 23d: She was delirious during the night, and refused food and medicine. At 6 A.M., T., 102.2°; P., 130; R., 56. At about this time the patient entered into a comatose condition and died at about 11 A.M.

Post-mortem by Dr. Boston, at 2 P.M. of the same day. I wish to state here that, unfortunately, owing to the building of a new pathological laboratory at this time, no cultures were taken. Heart: There was no hypertrophy; the muscular substance was pale; the coronary arteries were free. The left auricle was dilated, and seen from above the mitral orifice was found plugged by dark clot and large grayish-white vegetations. On sections, some of these were seen to be about one inch in length and friable, and at the base several distinct ulcers were recognized. The other valves were healthy. The spleen was enlarged, its pulp soft and reddish-brown; no infarcts were present. The liver was slightly enlarged, but contained no extravasation; its tissue was soft and light brown; no infarcts were present. Further examination revealed nothing of importance.

CASE II.—J. C——, male, aged nine years, white, American. Family history: His parents were born in Ireland. His father was by occupation a bartender, and died while under my care, at about forty-five years of age, with sclerotic kidneys and a dilated heart, probably due to overindulgence in alcohol. The boy's mother is living and healthy. He has two sisters living and in good health.

Previous history: He has had measles, chicken-pox, and whooping-cough; all under my observation. I emphasize this fact for the reason that I can speak positively concerning the absence of any previously existing heart lesion.

Present history: On November 4, 1898, I was called to the patient at his mother's residence and was informed that he had been ailing during the previous week, complaining of anorexia, general malaise, headache, etc. Dating from this time, for a period of exactly twenty-three days, the patient passed through a typical attack of typhoid fever. Relatively infrequent pulse, step-like rise of temperature during the first week, later morning temperature of 101° to 102°, evening temperature of 103° to 104°, diarrhœa, enlarged spleen, iliac tenderness, rose spots, response to the Widal test, and the diazo reaction were all present. At no time, however, were the symptoms unusually severe, nor was there any delirium.

On November 24th the fever terminated by lysis, and for six days an apparently normal convalescence continued. The tongue became clean, the appetite returned, and it was with difficulty that the boy was persuaded to remain in bed.

On December 1st the patient was suddenly seized with a rather decided rigor, which was repeated on one or two occasions during the following twenty-four hours. Immediately after the chill there occurred an apparently severe attack of pain, extending over the whole abdominal region. On the following day, and, indeed, until his admission to the Medico-Chirurgical Hospital on December 7th, these exacerbations of pain were repeated at intervals, and at one time seemed to be localized in the neighborhood of the appendix. Between the attacks the abdomen remained tender and tympanitic, and it was with considerable difficulty that on palpation the appendix was found normal. During this time the temperature on one or two occasions reached 102°, but was normal at times during some part of the twenty-four hours. The pulse, however, was now proportionate to the temperature, but examination of the heart revealed nothing abnormal. Increasing pallor and general debility became evident. The spleen, which had diminished in size, was apparently again becoming larger.

On admission to the hospital (December 7th) the temperature was 101.8°; pulse, 116; respiration, 24. On the following morning the temperature was 97°; pulse, 96; respiration, 24; and during the greater portion of his sojourn (thirty-three days) the temperature rarely reached 101°, and was quite often subnormal.

A blood examination made shortly after his admission showed white cells, 50,000 to the cubic millimetre; red cells, 3,500,000; hæmoglobin, 25 per cent. No microcytes, macrocytes, or poikilocytes were present. The examination of the urine was negative. The diazo reaction, however, was positive.

Under date of December 15th I find the following note: "His condition at the present time seems fairly good; he has had no pain for some time past. The temperature is still irregular and the pulse rapid. The action of the heart is tumultuous, but there is no adventitious sound. The spleen now reaches to one and one-half inches above a line drawn transversely through the umbilicus, the liver two inches below the ribs. He has had several severe nose-bleeds. His pallor is extreme. Marked pulsation of the carotids is noticeable. A second examination of the blood shows white cells, 44,000; red cells, 3,670,000; hæmoglobin, 30 per cent. Some enlargement of glands is present in the groin and axilla."

December 21st: "The spleen is one-half inch below the umbilical line and its upper border in the sixth interspace. It is smooth and thickened, but not particularly tender to the touch. The superior border of the liver is in the eighth interspace, the inferior border one-half inch above the umbilical line. Pitting on pressure is observed generally over the body, and the color is that of wax. No ascites is demonstrable. Throbbing of the vessels of the neck is noticeable. Tumultuous action of the heart is apparent; the apex is in the fifth interspace, and for the first time murmurs are heard: one is systolic in time and low in pitch, heard at the apex and not well transmitted. Another softer diastolic murmur is heard over the base. Bruit du diable is audible in the vessels of the neck. The axillary and inguinal glands are decidedly enlarged, somewhat soft to the touch, not movable, but not fused; the cervical glands the same, but to a lesser extent.

"A more detailed examination of the blood at this time shows the following: Red corpuscles, 3,100,000; white corpuscles, 49,000; hæmoglobin, 25 per cent. Poikilocytes are quite marked, megalocytes and microcytes quite numerous. No organisms can be detected.

"White cells: Polynuclear leucocytes, 79 per cent.; mononuclear, 2 per cent.; transitional, 2 per cent.; lymphocytes, 16 per cent.; eosinophiles, 1 per cent." I may state here that subsequent examinations of the blood did not vary much from the foregoing.

December 22d: During the night the patient was delirious and got out of bed during the absence of the nurse.

December 27th: The spleen reached one inch below the umbilicus. A distinct bulging was noticed and a grazing sound was heard over this region on auscultation.

December 29th: I find this important note: "A sudden and complete paralysis of the left side, with total anæsthesia of the left arm, was observed this morning. Heart murmurs continue as previously described."

The patient remained in much the same condition from this date, but with increasing prostration and frequency of pulse, until death occurred on January 10th.

The post-mortem was made by Dr. Babcock two hours after death under difficulties, the mother having absolutely refused permission for the same and remaining, indeed, in the waiting-room during this time. The following hurried notes were taken, but the heart, spleen, sections of the liver and glands, and a portion of the intestines are in my possession. The heart was normal in size, large masses of vegetation blocking the mitral

orifice. Several distinct ulcers existed between the outgrowths, one nearly the size of a turkey quill. The masses were grayish-yellow in color. The coronary arteries were free. The spleen weighed one and three-quarter pounds, its pulp was soft, and it contained three large yellowish infarcts. The liver was much enlarged, pale, swollen, and soft; it contained one infarct. The kidneys were somewhat enlarged and congested. In the intestines several distinct cicatrices from recently healed ulcers were observed in the ileum and other portions of the bowels. No infarcts were found.

Case III.—M. G——, female, married, aged twenty-one years, white, American. Family history: Her mother died of pneumonia; her father, three sisters, and one brother are in good health.

Previous history: She has had good health since childhood, with the exception of an attack of measles when ten years of age. Present history: In the early part of January, 1900, she was examined and passed by a physician for life insurance. On the 14th of March she miscarried of twins at about six months. She was out of bed on the 30th. On the following day she could not move on account of pains in the back and in the legs, which have continued more or less ever since. Her physician said this was rheumatism. Slight but offensive discharge from the uterus was present. She sweated at night. This condition of affairs continued, with increasing severity, for the following six weeks. There were pains in various regions, fever, sweats, and marked loss of strength and weight, so that at the time of my first visit she was extremely emaciated, slightly jaundiced, and so prostrated that she could not make the slightest movement. The expression of her countenance, as well as the general condition, was one of profound sepsis, and at my suggestion she was removed to my ward in the Howard Hospital on the following day.

May 22, 1900: Physical examination showed the lungs to be normal. The spleen extended two inches below the costal border. The liver was enlarged, but to a lesser extent. The apex beat of the heart was tumultuous and diffuse. No increase of cardiac dulness was found. A distinct murmur, systolic in time, was heard at the apex and transmitted to the left. Another systolic murmur was heard over a wide area at the base and was imperfectly transmitted. Temperature, 103°; pulse, 116; respiration, 29. The patient complained of dull pain in the region of the heart and of marked oppression.

The blood examination showed: Red corpuscles, 3,000,000; white corpuscles, 26,000; hæmoglobin, 35 per cent. Widal's reaction was negative. Streptococci were found in the blood.

The urine was negative as regards albumin and sugar, but gave positive diazo reaction.

The patient remained in the hospital for over six weeks (until July 12th). During this time the fever continued markedly irregular in type, reaching as high as 103.8°, and occasionally becoming subnormal. The pulse was rapid and, at one time, 148, soft, irregular, and compressible. Chilly feelings, followed by drenching sweats, were experienced, and during most of the time her condition seemed a most serious one.

The day following her admission, the question of curetting was decided negatively by my colleague, Dr. B. C. Hirst, but on different occasions no less than twenty abscesses, some deeply situated and others comparatively superficial, were opened in different parts of the body and streptococci were found in the pus.

I had at one time, when her condition appeared most desperate, made arrangements to inject some antistreptococcic serum, but found that the supply in the hospital had just been exhausted. The next day a slight improvement was manifest, so that the use of the serum was postponed.

During all this time the heart condition was as above stated. About June 22d the improvement became more decided, and the patient was at her request permitted to return home in a fairly good condition, on July 12th.

A recent examination (December 20, 1900) shows an increase of weight of twenty-five pounds. The heart reveals some slight increase in size, and both murmurs are still present.

All of the above cases presented points of particular interest. Case I. can be accepted as one of the typhoid type, and doubtless due to the poison of measles. This disease must be rare as a causative factor, for the examination of the literature at my command fails to reveal this relationship, with the following exceptions: James T. Whitaker states that "endocarditis very infrequently occurs in the course of measles, though cases have been noticed by Bouillaud, Stokes, and Roger. These, in fact, are the only ones I can find on record. Parrot did not find a single case of any form of endocarditis in eight hundred cases of measles." Anders mentions it as a possible cause. Even Osler, in his Gulstonian lectures on malignant endocarditis, does not mention the disease.

In Case II., first to be noted is the age of the patient—nine years. Osler tells us that there were only three or four patients under ten years in his collection of two hundred and nine cases. Samuel S. Adams reports a case in a girl aged six years, the only one treated in the Children's Hospital, D. C., since its organization in 1870, and after a thorough investigation of the literature on this subject he could tabulate only twenty cases (ten of males and ten of females) at or under the above age. Secondly is to be noted the typhoid fever, which I think was proved to have existed in this case. This disease seems much rarer than I had anticipated. Whitaker states as follows: "Typhoid fever is an infection which is rarely followed by endocarditis, and those cases reported will not bear strict analysis, as in many instances the diagnosis was based upon a bruit which might be otherwise explained." Osler says: "In the eruptive fevers grave endocarditis occasionally develops, in typhoid, in scarlet fever, and in variola; but in the cases I have analyzed these diseases appear of very trivial etiological significance." This case should, I suppose, be included in the simple pyæmic group, and yet had it not been for the differential count of the white corpuscles, and perhaps the number of the same, the clinical pictures would be almost typical of a case of splenic-lymphatic leukæmia. Grawitz states that the highest count of white cells in cases of malignant endocarditis has been found to be 44,200, the lowest 10,000. With this leucocytosis there is a decided reduction in the number of red blood corpuscles. It is worthy of note that, although the heart was repeatedly examined, no murmur could be detected until late in the disease.

In Case III., the interest consists in the fact that the recovery of the patient may throw a doubt upon the diagnosis. And yet, the previous successful examination of the patient for life insurance and the absence of evidence of compensatory hypertrophy on the one hand, and the positive nature of the symptoms for so long a period of time as detailed on the other, as well as the continued existence of a valvular lesion as recently determined, would supply an almost perfect record in favor of the views expressed. Besides which, other cases terminating in recovery have been reported by S. S. Adams, C. R. Gorwitz, H. Sainsbury, Leon d'Astros, and others.

The more modern views held regarding the relation existing between simple and malignant endocarditis make more easy the acceptance of the foregoing conclusion. For example, Lazarus-Barlow states that the difference between the simple and the malignant forms

depends upon the virulence of the micro-organisms or their toxins. The micro-organisms are almost always found in the vegetations on the valves in the infectious form, but also are frequently found in the so-called simple variety, and the same micro-organisms are found in both. When they act as irritants, inflammation results, and the case is one of simple endocarditis; but inflammation plus necrosis is septic endocarditis. Weichselbaum (quoted by Adams) claims that there is no essential difference, either histologically or bacteriologically, between the two forms; that the same species of bacteria are found in both, and that, in those cases in which the bacteria have not been found, they have either escaped detection or have died. Of his twenty-nine cases, he found the micrococcus lanceolatus in seven, the streptococcus in six, the staphylococcus pyogenes aureus in two, and in six various unusual bacteria; while in eight cases no micro-organisms were found. The most fulminating cases have followed staphylococcus infection. Streptococcus and pneumococcus infection was long drawn out, as a rule. Goldscheider claims that pneumococci in the blood always prove a profound infection and give an absolutely bad prognosis. When the ordinary examination of the blood has failed, Sittman's method should be tried. The blood may be taken from the median basilic vein with a sterilized syringe, mixed with melted agar, and be immediately plated; large quantities of blood should be used, so that the culture contains at least one-third blood. He states that the specific germ found in the blood gives decided evidence of the port of entry of the germ causing specific infection.

Dreschfeld agrees with the foregoing statements and mentions that most observers found but one organism in their cases, but admits that in some instances of infective endocarditis no microbes were found. In most cases the organism found in the diseased valve also invaded the infarcts and metastatic abscesses; those most frequently found were the streptococcus, the staphylococcus, and the pneumococcus. He further says that we may distinguish the following types of infectious endocarditis (*a*) primary; (*b*) as a complication of septic disease; (*c*) as a complication of pneumonia or meningitis; (*d*) as a mixed infection due to septic organisms, secondary to the acute infectious fevers, or secondary to rheumatic endocarditis or sclerotic conditions of the valves.

Adams mentions that a study of the experimental work of Netter, Ribbert, Frankel and Sänger, Prudden, Weichselbaum, Stern and Hirschler, Viti, and others, shows that true endocarditis can be produced in animals by injecting into the veins any one of the numerous micro-organisms, provided the heart valves are diseased, although Netter and Ribbert think a previous lesion is not essential; and Dreschfeld and others have succeeded in reproducing the disease in animals without previously injuring the valves.

Primary cases are rare. Osler states that it is engrafted upon a pre-existing valvular lesion in seventy-five per cent. of the cases.

Of the 209 cases in his collection, the tricuspid valve was involved in 19 cases, the pulmonary in 15, the aortic and mitral together in 41, the aortic alone in 53, the mitral alone in 77, the heart walls in 33, and in 9 cases he found the right heart affected alone. "These figures prove the involvement of the right heart out of all proportion to the left-sided disease in the less malignant or other forms of secondary endocarditis" (H. L. Elsner). Out of 802 benign cases recorded in the Munich statistics, the right heart alone was affected in 3.24 per cent. In 44 cases of ulcerative endocarditis the percentage of right-side lesion was 15.91 per cent. (Thayer and Lazear). Dawson Williams claims that, when the right side of the heart is attacked, it is due to secondary infection. Hall White explains that the specific micro-organism is thus carried by the veins to the right side of the heart.

Emboli occurred in one-fourth of all the cases tabulated by Sperling (quoted by Whitaker), and of these 84 cases, deposits were found in the kidney 57 times, in the spleen 39, in the brain 15, in the liver and alimentary canal 5, and in the skin 14 times.

Osler uses the term malignant instead of ulcerative endocarditis, as ulcers may not exist in all cases. Dreschfeld mentions that against the above it may be urged that some cases end in recovery; and again, that even the verrucose form may sometimes run a rapid or fatal course. He suggests the term infectious or infective.

It would seem that the recoveries are sufficiently rare not to invalidate the definition of the first term, and as I believe that even simple endocarditis is infectious, the substitute is even more objectionable.

Since the completion of the article, my attention has been called to Litten's report on endocarditis, before the German Congress of Internal Medicine.

His conclusions are somewhat similar to those that have been presented. His classification is as follows, on the basis of etiology:

I. Endocarditis benigna, which includes the following variations: rheumatica, peliotica, choreatica, gonorrhoica, scarlatinosa, morbillosa, variolosa, diphtheritica, typhosa, pneumonica, tuberculosa, e. influenzæ, and traumatica.

II. Endocarditis maligna. This is divided into (1) e. non-suppurativa, which includes e. rheumatica, e. choreatica, and e. gonorrhoica; and (2) e. suppurativa, septico-pyæmica—primary or secondary in any of the above forms. Benign and malignant gonorrhœal endocarditis are caused by the same agent, the gonococcus, the difference being merely one of degree, dependent on the virulence of the bacterium.

The Origin of Eczema.—According to C. F. Marshall the only rational view as to the origin of eczema is to consider it not of parasitic origin, but due to disordered metabolism, giving rise to irritating substances in the blood, probably uric acid, or one of the substances into which it becomes decomposed. The parasitic theory does not explain the frequently universal and rapid appearance of acute general eczema so well as the autotoxic theory. Again, acute general eczema often subsides in a remarkably rapid way under soothing remedies which contain no parasiticides. —*Treatment*, March, 1901.

STRANGULATED HERNIA IN INFANTS: DESCRIPTION OF A HITHERTO UNRECOGNIZED CAUSE AND SEAT OF STRANGULATION.*

By ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK,

ADJUNCT ATTENDING SURGEON, MOUNT SINAI HOSPITAL.

(From the First Surgical Division, Mount Sinai Hospital; Arpad G. Gerster, M.D., attending surgeon.)

During the past summer I had occasion to observe and operate on two cases of strangulated hernia in infants. In both cases I found the conditions to be so novel that I deem them of sufficient importance and interest to merit publication.

Case I.—On August 10, 1900, I was summoned to see August B——, aged four months, and obtained the following history: About two hours before I saw the child the mother noticed for the first time a small mass in the right inguinal region; this mass was pear-shaped, about the size of a small egg, and extended from the region of the inguinal canal into the scrotum. It was both painful and tender. The child had vomited repeatedly; its bowels, regular up till that day, had not moved. Gentle taxis was at once attempted, and this being unsuccessful, another attempt at reduction was made under chloroform anæsthesia. But this was also unsuccessful, and the child was admitted into Mount Sinai Hospital for operative interference.

On the same day (seven hours after the strangulation was noticed) I operated upon the child under chloroform anæsthesia. An incision was made over the length of the tumor, which was found to be a congenital hernia. As rapidly as possible the entire sac was liberated from the surrounding structures, when, without opening of the sac and without cutting or dilatation at the neck, there was no trouble in reducing the hernial contents. Ligature of the sac near the testis, and high up near the internal inguinal ring, and resection of the intermediate portion, followed by suture of the superficial structures, terminated the operation. The duration was twelve minutes. Perfect primary union resulted, and the patient was discharged, cured, fourteen days later.

Case II.—Milton F——, aged three months, was admitted to Mount Sinai Hospital on September 30, 1900, at ten o'clock in the evening, when the following history was obtained: The child was born prematurely, and almost mythical stories were related by his mother regarding his size and weight. At birth his length was said to have been no more than ten inches and his weight only one and one-half pounds. While he continued to live, he never thrived very much, so that his weight a few days before admission to the hospital was still only a trifle less than six pounds. For three days the child cried steadily and began to vomit, which symptom continued up to the time of admission. The mother was also certain that the child vomited fecaloid matter. On the morning of the date of admission the mother noticed for the first time a tense swelling in the left inguinal region. (It may, however, have existed there before, without her knowledge.) His bowels were moved by enema once, two days before admission, but refused to do so thereafter, in spite of efforts to do so by medication.

Status præsens: The general condition is very poor. In the left side of the scrotum there is a very tense, painful, and tender mass, about the size of an egg; the skin covering it, particularly in the lower portion, is red and œdematous. The mass is irreducible and presents all signs of a strangulated hernia.

Operation was performed immediately on admission, under chloroform anæsthesia. An incision was made over the mass in the left inguinal region, and the sac immediately opened. The aponeurosis of the external oblique was not divided, but there was at first no trouble in reducing the greatest portion of the hernial contents (large and small intestine), which were normal in appearance. There was, however, still one more loop of small intestine which resisted all attempts at reduction. I therefore extended the incision downward upon the scrotum, and found, beyond a constricting ring within the hernial sac, a loop of strangulated small intestine about four inches in length, of a deep purplish color, with its peritoneum still glistening. Under hot applications it rapidly regained its color. There was now no more difficulty in reduction, and this was rapidly accomplished. The testicle was also found to be gangrenous and was extirpated. On account of the bad condition of the child the sac was not extirpated, but merely sutured with a running catgut suture at the internal inguinal ring and the inferior portion also obliterated by suture. Suture of the overlying structures was done, with drainage at the inferior angle. The duration of the operation was twenty minutes.

The subsequent course was not so smooth as might have been desired, being marred by an intercurrent broncho-pneumonia; there was also considerable trouble in feeding the child. Both of these disturbances were taken care of by Dr. Koplik, visiting physician to the children's ward. On October 18th the child developed inflammation of the mastoid process, and was transferred for operation to the service of Dr. Gruening, with the herniotomy wound, with the exception of a minute superficial, granulating surface, practically healed.

Strangulated hernia in infants under one year is not by any means rare. Important and exhaustive studies upon it have been furnished to medical literature by Marsh,[1] Fere,[2] Knobloch,[3] Tariel,[4] Stern,[5] and others. The latest compilations of the subject originate from the pen of Dr. Charles W. Dowd,[6] of this city, who has been able to collect fifteen additional cases in 1897, and in a subsequent communication[7] added eighteen further cases, including two cases operated upon by himself. Though not overnumerous, the publications since that time describe strangulated hernia more in a general sense and, with few exceptions, do not give detailed descriptions of individual cases, so that it is difficult to establish satisfactory statistical data. We find among others that Coley[8] reports five cases in infants under one year; Fraenkel[9] has operated in four cases; Karewski[10] has operated in six cases; Funke[12] has operated in two cases; Tubby[12] has operated in two cases; Briscoe[13] has operated in one case.

This does not purport to be a complete list of the cases which have been placed on record since Dowd's last communication. In addition, there exist undoubtedly many scattered cases which I have not found, and which have never been reported. As the purpose of this paper, however, is not to draw such conclusions as can be obtained only from large statistical material, I have not found it necessary to republish all of the cases.

It is necessary to state at the outset that it is not to be denied that even infants of this very tender age may be afflicted with an acquired hernia; in which case they differ in no respect from similar herniæ in adults. But their relative frequency, when compared with that of the so-called "congenital" forms, is so small that for the purposes of this short article it may be left out of consideration; and I shall consequently confine my remarks wholly to the latter class.

Nor is it my intention to weary you with a detailed anatomical description of the congenital forms of

* Read before the Metropolitan Medical Society of New York, December 18, 1900.

hernia. There does not exist a single text-book upon descriptive or regional anatomy, which does not treat at some length of this topic; and one would naturally suppose that this matter would have been concluded long ere this. Important modifications have, however, been noted of late by various observers, and fully described by Bayer. My personal experience is limited to perhaps a dozen operated cases, hence I shall refer those further interested to Bayer's[14] and Bittner's[15] classical articles.

While the comparative rarity of strangulated hernia in infants of three and four months would alone be almost sufficient justification for the publication of these two cases, there is a further and more important reason for again bringing up this subject. This reason is the heretofore unrecognized location of the constriction low down in the scrotum, which, curiously enough, occurred in both of my cases.

As a rule, the strangulation occurs in all herniæ, no matter where located, either at the external ring or at the internal ring, or at the neck of the sac. The few exceptions to this general rule are caused either by newly formed inflammatory bands and adhesions, or more rarely by openings in prolapsed omentum.

A critical review of most of the reported cases regarding this point may tend to prove this statement:

1. In the monograph of Marsh (*loc. cit.*) the seat of the constriction is specified in 32 out of the reported 47 cases, viz.: In 20 cases it was at the neck of the sac; in 7 cases at the external ring; in 3 cases at the internal ring; in 1 case at both the external and internal rings; in 1 case at the conjoined tendon.

2. Tariel (*loc. cit.*) has ascertained the seat of constriction in 81 cases (under one year of age, 51 cases; over one year of age, 30 cases) of strangulated congenital hernia; and obtained the following results, viz.: In 58 cases it was at the neck of the sac; in 14 cases at the external ring; in 8 cases at the internal ring; in 1 case a "funiculo-testicular diaphragm caused the constriction."

3. Coley (*loc. cit.*) gives the cause of the strangulation in four of the five cases he publishes; and this is found to be the aponeurosis of the external oblique in all cases.

There is evidently an important discrepancy between Coley and previous observers. Coley tries to explain this by suggesting insufficient observation, because he claims that in a majority of the cases compiled by Tariel the patients were operated upon without a free division of the aponeurosis of the external oblique, thereby preventing a thorough examination. Certainly no responsibility for this matter can be attached to Tariel, as a majority of the cases he reports were taken from other publications, and he gives the site of strangulation only as recorded. But excluding from his figures the cases compiled from the literature, and using as a basis for argument only the cases in which he witnessed the operation by M. Broca at the Hôpital Trousseau, and which were really the incentive for his dissertation, we find as the seat of the constriction the neck of the sac four times out of five cases. Coley's standpoint can hardly be assumed to be correct, particularly when it is taken into consideration that M. Broca himself operates in his cases of hernia also by free division of the external oblique. This is what Tariel has to say regarding this point: "M. Broca, who, in order to reach the neck of the sac, liberally divides the aponeurosis of the external oblique in all cases, whether strangulated or not, has noted that after perfect exposure of the sac, and without any muscular pressure whatever, the constriction persisted in the form of a narrow band (*bride*), reaching into the interior of the sac; and it was only after cutting this band (*bride*), in the neighborhood of the sac, that the strangulation could be relieved."

4. I have searched the records of 38 other cases regarding this point, and found that the seat of the constriction was not stated in 26 cases, was given as the internal ring in 6 cases, as the external ring in 4 cases, and as the neck of the sac in 2 cases.

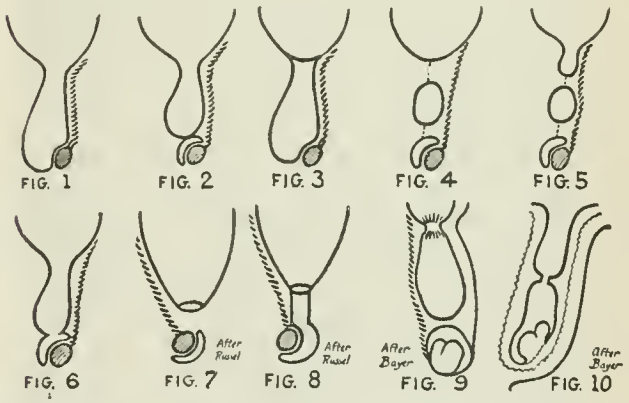
However, no matter which point is decided to be the seat of the constriction, this much is certain, that in by far the greatest majority of the observed cases the strangulation occurred either at the external ring, or at the internal ring, or at some point between these two. You will, therefore, readily agree with me that I was somewhat nonplussed, and at a loss to account for the strangulation in both of my cases, which occurred in the scrotum proper and at a considerable distance away from the external inguinal ring.

How can we account for this unusual exception?

For the better understanding of the possibility of such an occurrence it is necessary to go back to the developmental stage of the organs in this region.

It would exceed the limits of this short communication to give you a detailed description of the descent of the testis. Suffice it to recall for the moment that the testis in its descent to the scrotum, shortly before or shortly after birth, is preceded by a prolongation of the peritoneum, the processus vaginalis.

What, however, does materially interest us is the subsequent metamorphosis which takes place in this extruded portion of the peritoneum. The normal proc-



ess is that it becomes shut off just above the testis and forms a partial serous investment for this organ, the so-called tunica vaginalis. Furthermore, it becomes closed off also at the internal inguinal ring, while that portion lying between the internal ring and the tunica vaginalis becomes completely obliterated.

This is the normal process. There are, however, a number of deviations from the normal which are very important and may give rise to a number of anomalies.

1. The processus vaginalis may remain open in its entire extent. The testicle in this case is then partly within the sac. If it be open also at the internal inguinal ring, and an exciting cause be given, the abdominal contents may very readily enter, giving rise to a so-called "congenital hernia" (Fig. 1). In this case the hernia is in contact with the testis.

It may not be amiss right here to explain why in using the term "congenital hernia" I nearly always precede it with the word "so-called." First of all, the term "congenital hernia" has of old been applied to this particular form of anomaly; and while the other forms, to be shortly described, are also dependent upon some congenital fault, it is perhaps just as well to retain the time-honored term "congenital hernia" for this particular variety. As a mater of fact, the entire terminology could well stand revision, as in a stricter sense none, or at most the very fewest, of the described cases are congenital herniæ. The only part of most of these herniæ which is really congenital is the sac, while the hernia proper is acquired.

2. The processus vaginalis may close off at its lower end, forming a complete tunica vaginalis for the testis;

but it remains patent at the internal ring. The occurrence of a hernia in such a case is just as probable as in the first case, but with this difference, that the hernia is not in contact with the testis, being separated from it by the tunica vaginalis. This hernia has received the name of "hernia into the funicular process" (Fig. 2).

3. The processus vaginalis may remain open at its lower, but becomes shut off at its upper end. Should a hernia arise in this case it would become invested by a part of the peritoneum, which is extrinsic to the vaginal process. This form of hernia is called an "infantile hernia," or "hernia encystica Cooperi" (Fig. 3).

4. The vaginal process may form the tunica vaginalis as is normal, and may also become shut off at the internal inguinal ring; but the intervening portion does not become obliterated. Should, in consequence of any subacute or chronic inflammatory process, an exudate take place into this unobliterated portion, it will give rise to a "hydrocele of the cord" (Fig. 4).

5. The vaginal process may form the normal tunica vaginalis; and the upper part becomes shut off at, or in the neighborhood of, the external inguinal ring; while the most superior portion remains patent and communicates with the general peritoneal cavity. If now in this case the formation of a hernia be presumed, and also, for the sake of clearness, an exudate into the closed portions of the processus vaginalis, it will be apparent that we will have to deal with three separate swellings, viz., going from below upward, (1) a hydrocele of the tunica vaginalis; (2) a hydrocele of the cord; (3) a form of congenital hernia (Fig. 5).

The five abnormalities just enumerated are well known, and have so frequently been observed and described as to require no further comment, and may well be called the normal abnormalities. On the other hand, there may occur also abnormal abnormalities, and it is these in which we are particularly interested, as it is only by understanding these that we can account for the strangulation in my cases.

6. In the course of development the processus vaginalis may begin the shutting off of the normal tunica vaginalis, but the process may stop before it is entirely completed. The result will be a sac of the usual congenital variety (Fig. 1), but with this important difference, that it will be constricted in its lower portion (Fig. 6). In other words, the sac may not improperly be compared to an hour-glass open at its top; the size of the two halves varying, dependent upon the different theories which have been proposed as regards the exact mode of development.

The opinions regarding this point are not unanimous. I have obtained the following views:

Jossel-Waldeyer[16] says: "Shortly before or shortly after birth that part of the processus vaginalis which lies nearest to the testicle becomes closed off and forms the tunica vaginalis. Later, as a rule, that part lying in the inguinal canal becomes closed off, while the middle portion which lies in the scrotum remains open longest."

Merkel[17] says: "At about the period of birth the processus vaginalis becomes closed. The closure begins about the middle of the spermatic cord and advances in both upward and downward directions."

Lockwood[18] has this to say regarding the closure of the processus vaginalis: "There seems to be, as others have remarked, a strong tendency for it to close in two places, which are some distance apart; namely, just above the testicle and near the internal ring."

If it be presumed for the moment that Jossel-Waldeyer's opinion is correct, then the sac in this form of abnormality would consist of a smaller inferior portion and a larger superior portion. If, however, Merkel's theory is assumed to be the true one, then the two halves would be of more nearly equal size; while if Lockwood's opinion proves to be correct, then we may even have two constricting rings—one at the internal inguinal ring and one just above the testicle.*

This is my explanation of the occurrence of the strangulation low down in the scrotum in both of my cases. It is of course unfortunate that I cannot bring absolute proof for my explanation of the existence of such a sac, in the form of a demonstration ad oculos. As an excuse I must say that most of what I have said has been an after-thought subsequent to the operation; for there is very little opportunity for study of this nature in the heat of operation, during which one's mind is concerned mostly with the operative technique, and with the time in which to get through. Moreover both of these cases were strangulated herniæ, and in consequence the pathological specimens and proof were destroyed by the operation; in Case I. by the liberation of the entire sac from the surrounding structures, and the manipulation for the reduction of its contents; in Case II. by direct division of the constricting ring.

Though I should be very glad to be in position to bring confirmation for the occurrence of this form of strangulation, in the literature, I have been unable to find a single authentic case recorded. Its probability, however, is decidedly indicated in the following cases of reducible inguinal hernia:

1. Bittner[19] reports a case (Case XXX.) in which the hernial sac communicated by a fine opening with the hydrocele of the tunica vaginalis.

2. Bayer (*loc. cit.*) in speaking of the persistent vaginal process discusses, among others, circular constrictions, and brings forth two examples in illustrations. In the first figure (Fig. 9) the constriction is high up near the inguinal ring, while in the second (Fig. 10) the constriction is about midway between the testicle and the inguinal ring. The author does not say anything further of these cases, but, to judge from the illustrations, it is perfectly clear that a knuckle of intestine or omentum may very readily become strangulated if it should slip beyond the constricting ring.

3. Russell[20] illustrates by diagram two very interesting cases. "In the first case (Fig. 7) the tunica vaginalis has formed, but the apex of the upper part of the processus vaginalis has failed to become completely closed, and terminated in a circular fibrous ring. In the second case (Fig. 8) the same sort of arrangement existed as in the first case, but with the additional circumstance of interest that the fibrous ring is the only part of the funicular process in which obliteration has been attempted, with the result that the hernia has been permitted to descend as far as the constriction, while all the rest of the funicular process below the constriction persisted as a congenital hydrocele."

The discovery of this case in the literature was an exceedingly valuable one to me, as it corroborated the findings in my case perfectly. Let us go just one step further. Given an exciting cause in increased intra-abdominal pressure, a portion of the hernial contents is pushed beyond the fibrous ring where it becomes at once strangulated, and then we have a picture which closely resembles those of both of my cases, and particularly that of Case II.

Cæsarean Section for Fibrocystic Uterine Tumor.—George L. Brodhead reports a case in which this operation was successfully performed. The patient was given ether; then, under constant irrigation with a hot decinormal saline solution, an incision six inches in length was made in the median line and the uterus exposed. Under constant irrigation the uterus was incised, the sac opened, and the child lifted out of the uterus. The placenta and membranes were removed manually. The tumor, about the size of an orange, was adherent to the rectum, but was detached and removed. It broke at one point, and some of it contents escaped, but no harm was done. The patient was taken to her bed in excellent condition, a little less than an hour having been required for the whole operation. Her recovery has been uninterrupted and the child is doing well.—*The Post-Graduate*, March, 1901.

The Value of the Tuberculin Test in Recognition of Latency or Quiescence in Tuberculosis of the Bones and Joints.—Charles H. Frazier describes the methods of using the tuberculin test, not as the means of revealing the presence of a focus in the incipiency of the disease, but as a means of determining whether, when the disease has apparently run its course and subsided, the process is in a state of quiescence, of latency, or whether resolution with total disappearance of tuberculous material has occurred. If the tuberculin test can be relied upon as he believes it can, there exists in those who have been subjects of tuberculous bone and joint disease a tuberculous focus, deep-seated, probably in the lymphatic system, which may have been the source of infection of the so-called "primary" bone or joint lesion. The existence of these tuberculous foci in the lymphatic system would serve to stamp as unreliable the tuberculin test when employed for the demonstration of the presence or absence of tuberculous lesions in other tissues of the body.—*University of Pennsylvania Medical Bulletin*, March, 1901.

Veratrum Viride; its Undeserved Neglect.—E. W. Saunders makes a plea for the more frequent use of this remedy which he considers one of the most valuable drugs at our disposal. It is especially valuable in puerperal eclampsia and in pneumonia. In the former disease chloroform should be given, followed at once by veratum in large doses, so that the pulse may be maintained at the normal rate. The lessening of the vascular tension quiets the excitement of the cerebral cortex, causes free sweating, and increases the elimination of toxic material through the kidneys. In pneumonia, veratrum diminishes the pulse rate, lessens arterial pressure, diminishes the number and depths of the respirations, reduces the temperature from one to three degrees, gives a feeling of well-being to the patient, increases the quantity of the urine, quiets nervous excitement, and leads to a precocious and partial hepatization in the lung. Our course should be to watch the temperature and the pulse, and to use both as an indication for the use of the drug. When consolidation is complete, nothing can be gained by veratrum; digitalis, caffeine, camphor, and strychnine are then indicated.—*St. Louis Medical Review*, March 23, 1901.

Reduplication of the First Sound of the Heart.—C. C. Gibbes holds that we have two forms of reduplication of the first sound: first, the muscle vibrations, which have a dull rumbling character; secondly, the valve tension which is clear and high pitched in tone. Barr and Bramwell agree that "the right ventricle, by reason of the increased blood pressure in the right cavities of the heart, is first stimulated to contract," but they do not state that this contraction of cardiac muscle is audible. Gibbes is decidedly of opinion that it is, and believes this form of reduplicated first sound to be quite as common as the well-recognized reduplication of the second sound. It is frequently heard over the right ventricle in cases of anæmia when the heart is dilated and the second sound reduplicated, consisting of a low rumbling sound extending backward from the first sound and occupying the latter portion of the diastole. It is heard also under various other conditions, such as degeneration of cardiac muscle in typhoid convalescents, and in old-standing cases of bronchitis and emphysema when the right ventricle is beginning to fail. If degeneration of the cardiac muscle is present, the muscle sound is feeble, and may be nothing more than what Sibson describes as an absence of silence. When, on the other hand, the muscle is hypertrophied, it is of much greater intensity, and may in some cases closely imitate the presystolic murmur of mitral stenosis; Flint's murmur and the other presystolic murmurs that are not caused by mitral stenosis being, Gibbes believes, due to this form of reduplication. In mitral stenosis itself they impart the uniformly crescendo character to the murmur, and are the cause of the intimate connection of the auriculo-systolic murmur with the first sound.—*Medical Times and Hospital Gazette*, March 16, 1901.

The Vicarious Absorption of Oxygen in Pulmonary Obstruction.—Perry E. Doolittle claims that in diseases in which lack of oxygenation becomes a dangerous factor, such as laryngeal diphtheria, bronchopneumonia in infants, and double pneumonia in children, the internal exhibition of hydrogen dioxide is of great value. It readily parts with its oxygen, and, indeed, in its full strength is so active that to prevent oxidation of the tissues it has to be diluted. The three-per-cent. dioxide of medical commerce can be diluted about four to one. By administering the dioxide in sufficient quantity per os or per rectum, or both, we give the heart a healthy oxygenated blood to work on, we remove the demand in the system for more oxygen, thus taking away the necessity for overwork of the heart, we relieve the working air cells from the overstrain, and favor early resolution of the disease areas by supplying them with healthier blood. Its administration does not interfere with that of oxygen by innalation, or with any other internal remedies which may be indicated, and in its free use the author believes that we have a means of tiding over the acute stage of pneumonia. The author reports two cases of its successful use.—*Dominion Medical Monthly*, March, 1901.

Chloretone in Dusting-Powders.—The employment of this agent for the purpose named is commended by E. H. Siter, who says that its use in dusting-powders for painful granulation wounds has been wonderfully

successful as far as analgesia is concerned. It does not seem to delay union or granulation, and it can be used in combination with almost any dusting-powder. It cannot be said, however, to hasten granulation, and, as far as he has observed, all it does is to mitigate or entirely allay pain in the majority of cases. This, after all, is a good deal gained for the patient and the physician. He has failed to obtain any action from the remedy used in solution for local anæsthesia. —*Therapeutic Gazette*, March 15, 1901.

A New Remedy for Hemorrhoids.—E. V. Hall, after experiencing the cooling effect of Echinacea angustifolia on a suppurating wound of his own finger, was led to use the drug in cases of hemorrhoids. The following is the formula used:

℞ Ext. echinaceæ angust. fl. ..... ʒ i.
Ext. hamamelidis virg. fl. ..... ʒ ij.
Aquæ destillatæ. ..... ʒ i.
M. S. Inject two fluidrachms after each stool.

Immediately after the use of the mixture a slight burning sensation is felt by the patient, but this is soon replaced by the peculiar cooling effect of the echinacea. Although the author has not yet had extensive experience in the local use of this drug, such as he has had, has been perfectly satisfactory, and he declares that he shall continue to use it, hoping later to make a more valuable report.—*The Cincinnati Lancet-Clinic*, March 23, 1901.

Silver Salts in the Treatment of Catarrhs of the Upper Air Tract.—E. B. Gleason says that whether the irritant or sedative effect of silver nitrate predominates, depends largely upon the character of the epithelial layer of the mucous membrane to which it is applied. If a sixty-grain solution be painted upon the posterior wall of the pharynx, the irritating quality is manifested and produces discomfort, persisting for some time. If, however, this solution be painted upon inflamed tonsils and the inflamed lateral wall of the pharynx, the primary irritant qualities of the nitrates are scarcely perceptible, and the procedure is followed by a sense of great relief and comfort. Painting the lateral walls of the pharynx with a sixty-grain solution two or three times a day is one of the best methods of aborting acute pharyngitis and tonsillitis. The reddened parts are at once blanched, partly as the result of the astringent effects of the silver and partly as the result of the formation of a closely adherent organic compound of the silver. The sedative effects of the application are so marked that the patient is usually able at once to swallow without much discomfort. The posterior wall of the pharynx should then be painted with a twenty-grain solution of protargol. This treatment, if repeated twice or thrice a day for two or three days, will in a large proportion of cases abort phlegmonous tonsillitis.—*Therapeutic Gazette*, March 15, 1901.

Ulcus Rodens Corneæ.—Schmidt-Rimpler reports two cases of this rare affection, which is not to be confounded with ulcus serpens, nor with the shallow marginal ulcers seen in old people, nor with chronic peripheric furrow keratitis. The rodent ulcer always begins along the corneal margin as a narrow but extended ulceration which gradually approaches the centre of the cornea. As a rule, the entire cornea becomes leucomatous, but in some cases there is partial leucoma. The disease may attack old or young, but it has never been seen in children. The etiology is still uncertain. Microscopically, undermining of the central margin of the ulcer is seen; there is actual elevation of the epithelium, which appears at first without any infiltration of the corneal tissue. At the peripheral margin of the ulcer, however, there is a hemispherical elevation, caused by proliferation of the epithelium, and particularly by the enormous development of new vessels. The moderate depth of the ulcer is revealed in the preparations. The retina is seen to be somewhat affected. The most rational treatment would seem to be cauterization and scraping, and possibly covering the ulcer with conjunctiva, although one cannot always expect a good result. As the deep layers of the parenchyma of the cornea and the membrane of Descemet are preserved, von Hippel's method of corneal transplantation might well be tried.—*Archives of Ophthalmology*, March, 1901.

The Myocardium in Infections, Intoxications, and Poisoning.—Giuseppe Giacomelli concludes his study of the subject by the statement that the interstitial connective tissue and the blood-vessels are rarely altered, but that lesions are constantly found in the fibres themselves. These lesions vary from simple atrophy and disappearance of striation to fatty and hyaline degeneration, segmentation, and destruction of the fibres. No special anatomical changes characterize any given infection or poisoning. The lesions found in the human heart can be produced experimentally in animals. The changes in the cardiac fibres are due to the direct action of the bacterial toxin or the organic or mineral poison on the fibre itself. These lesions are in themselves sufficient to produce cardiac paralysis.—*Il Policlinico*, February and March, 1901.

Hæmatoma of the Abdominal Walls Complicating Pregnancy.—W. Stoeckel describes two cases of a lesion which he thinks has not hitherto been described. In each instance a number of days before labor a large, flat, disc-like swelling appeared over the lower abdominal region, increased in size for a day or two, and was accompanied by moderate pain and febrile disturbance. At the time of observation no tenderness was present, and the tumors could be distinctly made out as being situated in the abdominal wall itself. After confinement, the masses decreased further in size, so that all possibility of their being new growths could be excluded and a diagnosis of fluid exudate was made. On incision the sheath of the rectus muscle was found filled with partly clotted blood, which was removed, the cavity curetted and packed. The sacks were quickly and completely obliterated and perfect union with a linear scar obtained. The point that makes the cases so anomalous is the fact that absolutely no cause for the effusion could be found, though all possibilities of a local trauma of any sort or systemic lesions were carefully inquired into.—*Centralblatt für Gynäkologie*, March 9, 1901.

The Operative Treatment of Congenital Luxation of the Hip.—A. Codivilla says that in children between the ages of three and twelve years, reduction may often be accomplished without cutting, and be maintained with good functioning powers in fifty-three per cent. of the cases. In the remainder the luxation returns, but in lesser degree than at first. To prevent this relapse, plaster apparatus must be used to fix the joint in the first position of abduction and internal rotation, for four or five months. In cases of extreme torsion of the upper end of the femur, osteotomy may be necessary to restore the normal relations between the two ends of the femur. The best incision in cases of operation on the joint is the antero-external, along the anterior border of the fascia lata, continued upward along the iliac crest, with detachment of the fascia lata, and a part of the gluteus minor and medius from their iliac origin. The wound is to be closed without drainage.—*La Riforma Medica*, March 6 and 7, 1901.

CYCLIC ALBUMINURIA.

IN 1885 Dr. Pavy read a paper at the annual meeting of the British Medical Association, in which he propounded a new theory as to the occurrence of albuminuria in the apparently healthy; that is, in those persons presumably not afflicted with organic disease. Physicians for many years previous to that date had been aware that albumin appeared at intermittent intervals in the urine of individuals who seemingly were in a normal state of health, but owing to the somewhat casual manner of examining urine in bygone days the fact attracted but little attention.

When, however, a strict clinical examination of urine became more generally adopted as a part of the routine of practice, notice was soon drawn to the frequency with which "intermittent albuminuria" occurred, and the phenomenon was made the subject of much investigation, and many reasons were offered in explanation thereof.

Dr. Pavy, who had observed the tendency to the periodic recurrence of albuminuria, especially in the morning, concluded that it must be connected with cyclic change occurring at that period. At the time of the announcement, and for a few years after, Dr. Pavy's theory was considerably criticised, but now it is widely accepted as correct, so much so, indeed, that the condition is frequently referred to in Europe as Pavy's disease.

Since 1885 the matter has been discussed in medical circles in every civilized country, European physicians being particularly prominent in endeavoring to clear up its obscure points. Many facts relating to this form of albuminuria have been collected, and various theories with regard to its causation and significance have been advanced. Literature, contributed by native writers, bearing upon cyclic albuminuria, is neither copious nor exhaustive. Osler has written concerning it, as have Davis, French, Delafield, and others; but for the most valuable information regarding the condition, recourse must be had to the recorded researches of medical men of Europe and Great Britain, including Tessier, Lacour, and Marie, of France; Huebner, Reckman, and Heller, of Germany; and Ralfe, Moxon, Sterling, Hawkins, and Sutherland, of Great Britain.

Among the latest and clearest presentations of the subject as regards our present-day knowledge are a short article by Dr. Herbert P. Hawkins, of London, which appeared in the *British Medical Journal*, December 9, 1899, and a small book written by Dr. G. A. Sutherland, also of London, published at the end of 1900.

In the first instance, it must be premised that there is universal agreement as to the accuracy of Pavy's description of the characteristic features of this condition, which is as follows: "In the early morning the urine is free from albumin. Alubmin then shows itself, it may be at 9, 10, or 11 A.M., or not till the early part of the afternoon. After reaching its maximum, it declines, and often by the evening it has disappeared. It is rare to find that it has not disappeared by bedtime." Then there should be no ambiguity with regard to the sense in which the word "albuminuria" is used, as Dr. Hawkins emphatically says: "It is used in the clinical sense and not in a laboratory sense." From a laboratory point of view the presence of albumin in urine is the rule rather than the exception.

So far as the age incidence of albuminuria is concerned, Hawkins says: "The age at which it commences and the absolute frequency of its occurrence are unknown, because the condition is nearly always discovered accidentally." In the tables given by Huebner and Sutherland, the striking feature is the preponderance of these occurrences during adolescence. As regards the comparative frequency of sex incidence, Hawkins holds the view that our information is necessarily so imperfect that no definite statement can be made, while Sutherland, too, is by no means convinced of the validity of the prevailing belief that the "albuminuria of adolescence" is essentially an affection of the male sex—indeed, his own experience points to an opposite conclusion.

Both Dr. Hawkins and Dr. Sutherland agree that morning albuminuria is dependent on rising up, the standing or moving about in the early part of the day, and that it is not influenced by the taking of food. Dr. Sutherland is of the opinion that it is not dependent upon, although probably increased by, walking-exercise. Dr. Hawkins says all our evidence tends to indicate: (1) That the immediate cause of the escape of albumin is temporary impairment of the efficiency of the epithelium of the glomeruli, but (2) that the impairment in epithelial efficiency is itself the result of temporary alterations in the blood pressure in the glomerular capillaries. In other words, the actual seat of the trouble appears to be in the vasomotor mechanism, which regulates the blood flow into and out of the glomeruli, and not in the kidney structure. Dr. Sutherland coincides in opinion with Huebner, Marie, and others, that there is a general pathological condition present, to which the various symptoms may be ascribed, produced by instability of the nervous system, and is further disposed to think that the affection represents a condition of toxæmia, similar to, or identical with, the uric-acid diathesis. Upon the question of prognosis it is, of course, well known that there is a wide divergence of opinion, the majority of those who have made a study of this form of albuminuria holding that it is not unfavorable. Dr. Hawkins on this point gives a judiciously qualified

pronouncement. He is not too optimistic, but, upon the whole, he is inclined to look upon the bright rather than upon the dark side. Dr. Sutherland naturally does not commit himself to the expression of any definite views; but, as may be judged from the position he takes with regard to the etiology and pathology, he does not anticipate an ultimate, complete recovery. He adds the saving clause, nevertheless, that there is no evidence of any one having died of cyclic albuminuria, nor of Bright's disease supervening upon it, and thinks that a person in this state will under suitable surroundings and leading a careful life enjoy average good health. Neither of the above-mentioned physicians opines that medicinal treatment is either necessary or useful. Perhaps the greater number of physicians in this country will bear out the views of Dr. Hawkins as to the causation of cyclic albuminuria, rather than those of Dr. Sutherland; but why, if the immediate cause of postural albuminuria be variation in the blood pressure in the kidneys—as is the common belief—is not more attention paid to examinations of the blood pressure, as indicated by the pulse, at different times in the day? It is certainly in some degree curious that after all these years of investigation a more accurate knowledge of cyclic albuminuria has not been attained. At present no one knows with certainty whether it is physiological or functional or tending toward organic change in the kidney. It is self-evident that the subject is of the very first importance, and its final settlement would take rank almost with the greatest medical discoveries of this or any age. The researches of such earnest and capable workers as Dr. Hawkins and Dr. Sutherland are a good augury that such a result may be eventually reached.

THE INDISCRIMINATE SLAUGHTER OF WILD BIRDS.

Public opinion is gradually veering toward the conviction that the careless and needless killing of wild birds should be stopped, or at least be restricted to reasonable bounds. There is an old saying that a typical Englishman when he goes out in the morning usually remarks, "It's a fine day" (or "a wet day," as the case may be). "Let us kill something." This blood-thirsty instinct would appear to be almost as fully developed in the American. According to trustworthy accounts, the massacre of sea birds has been carried on in so reckless a manner that many breeds bid fair to become extinct. The breeding-season is that generally chosen for this sportsmanlike pastime, as then the birds come unwarily within the range of shotguns, the result being not only the death of the birds themselves, but the spoiling of eggs and the destruction of the young. The American Ornithologists' Union has been and is doing all in its power to check the probable extinction of sea birds by these means. The union has been successful in prevailing upon the legislatures of twenty-two States to pass laws for the protection of sea birds; but in Louisiana, in the swamps of whose coasts wild birds of all kinds most abound, the authorities have refused to grant protective legislation. The committee, therefore, appointed by the union to devise means of preservation for the feathered inhabitants of this region has decided to hire wardens to guard the sea birds while they are on their breeding-grounds. As the New York *Sun* of Sunday, March 31st, points out, this scheme is now practicable, much of the Gulf swamp land having passed into the hands of private individuals, with whom the Ornithologists' Union has come to an agreement to prevent trespassing; and by shutting out the hunters from the marshes, it will become impossible for them to kill the sea birds which breed on these lands.

The Lacey act also is a powerful instrument for the protection of birds and beasts, as it makes it a punishable offence to export from a State any bird or animal unlawfully killed therein, or to receive such a bird or animal in any other State. The committee is sanguine that the vigorous enforcement of this law by the United States department of agriculture, which has the matter in charge, and the proposed extension of the warden system, will in a very short time break down the whole plume trade so far as it lives upon the birds of the United States.

That these anticipations may be fully realized will be the earnest desire of those who deprecate the unreasoning slaughter of beautiful and useful sea birds.

THE PATHOLOGY OF THE SO-CALLED FUNCTIONAL NEUROSES.

Of the essential nature of life, little of a definite nature is actually known. The most that can be said of it in this connection is that it represents a mode of motion, a form of force, whose activities are exhibited in diverse ways, and the results of which may be evident, while the underlying mechanism is concealed from view. Life is seen in its simplest form in the cell. Organs are but aggregations of cells, and the animal organism but an aggregation of organs intimately connected and related. That life must be attended with certain changes in the media through which its activity is manifested would seem almost axiomatic. Its normal manifestations we know as function, its aberrations as disease.

The beginnings of disease must necessarily consist in undiscernible alterations in cellular structure and function, and it is probable that changes of this character underly the so-called functional disorders; namely, those unattended with evidences of structural or organic lesions. Recent advances in staining-methods have, in fact, helped to disclose minute changes in cells subjected to various morbific influences, and thus lend support to the view briefly expounded. Such alterations in cellular nutrition may result from the action of substances normally generated within the body, but now produced in excess or in deficiency, in consequence of some derangement in metabolic equilibrium, or in themselves abnormal, or introduced from without in connection with infection or intoxication.

As bearing upon this subject, Dr. Theodore Klingmann (*American Journal of Insanity*, vol. lvii., No. 3, p. 519) has recorded the results of some observations

on the cells of certain algæ and protozoa. It was found that a variety of changes could be induced by artificial means: (1) Changes identical with the physiological appearances occurring in the cells when they die gradually from natural causes; (2) changes of a purely chemical character; (3) changes of a pathological nature due to toxic substances—the results varying with the intensity of the operating influence. In one series of observations metallic substances were employed to induce the changes described. In the second series blood serum obtained from patients suffering from various forms of so-called functional, nervous, and mental disorders was substituted. Analogous results were obtained in both series of experiments. A great variety of pathological conditions was found in the ganglion cells of rabbits and guinea-pigs treated with injections of toxic serum in varying dilution, the form of chromatolysis varying with the strength of the serum and the period of its activity. The use of blood serum from healthy individuals, on the contrary, yielded negative results.

THE PRISON ASSOCIATION OF NEW YORK SING SING PRISON.

A MEMORIAL has been presented by this association to the New York legislature, respecting the condition of the State prison at Sing Sing. The association's investigating-committee, the sanitary engineer, the warden, and the physician of the prison all concur in a severe indictment of the existing unhealthful plight of the institution. Their reports show that Sing Sing prison is absolutely unfit for human habitation. Sufficient light is entirely lacking. The cells are dark, unventilated crypts, in which men are compelled to exist on one-third the amount of air necessary for the average human being. Even this pitifully small supply of air is vitiated by foul and poisonous odors from the "backing up" of sewage and the deleterious emanations from defective drainage diffused throughout the prison. These dangerously unhealthful conditions which have engendered typhoid fever and tuberculosis are aggravated by the enforced overcrowding, by which two men are obliged to sleep together in a space that might answer for a dog's kennel, but into which no thrifty farmer would think, in these days, of immuring one of his cattle. Mr. Charles Wingate, the sanitary engineer, condemns the construction and arrangements of the prison, in unqualified terms of strong disapproval.

These facts were laid before the State board of health, which body, as a result of independent investigation, fully endorsed the findings of the committee of the Prison Association. Although the legislature has been yearly notified for some considerable period of the unhygienic state of Sing Sing prison, up to the present time no action has been taken. Stress has been laid in many medical journals recently, upon the fertile field afforded by ill-ventilated and overcrowded prisons as a means of propagating and spreading disease, and especially of tuberculosis. A significant object lesson of the truth has been given by the prisons of Alabama. It has been pointed out time and again that not only is a prison of this description inhuman to a degree, and dangerous to the health of the unhappy culprit incarcerated therein, but is also a distinct menace to the community. For all reasons then, for moral, physical, and economical, the fitting and obvious course of the legislature would appear to be to order Sing Sing to be razed to the ground, justly condemned as a relic of the dark ages of penology, and to erect in its stead on a suitable site a building constructed in conformity with the latest sanitary principles.

The urgent appeal of the committee of the Prison Association that a commission be appointed to consider what steps are necessary for the improvement, reconstruction, or centralization of the penal institutions of the State is founded upon a sound and reasonable basis and is deserving of the close attention of the authorities at Albany.

News of the Week.

Sterilizing Money.—The Cheshire National Bank, of Keene, N. H., has recently taken a very unusual precaution. Scarlet fever is epidemic in that town, and to prevent its spread the bank has put in a sterilizing oven, in which all the money which passes through its hands is to be sterilized.

Public Opinion on Bird Slaughter.—The New York *Evening Post* quotes the following denunciation of trap shooting which will find an echo in the hearts of all reasonable and humane members of the community: "Massachusetts has a law against the trap shooting of live birds, and the practice should not be tolerated in any State; and it will not be any longer in New York if public opinion, which appears to have become thoroughly aroused on the subject, is rightly directed. The gratification of a brutal instinct on the part of a few should not be permitted at the expense of a wholesale cruelty to helpless victims and a shock to public sentiment."

Stony Wolde Sanatorium.—The energetic measures now being taken in all parts of the world for the checking of consumption are evidenced by the various philanthropic schemes that are multiplying almost daily to attain this result. The New York *Evening Post* refers to one of the latest of these in this State thus: "A pressing need of the times is the establishment of sanatoria for working-girls, young married women, and children suffering from tuberculosis. For the purpose of founding an institution of this kind a committee of women has been formed, known as the Stony Wolde Sanatorium Building Fund Committee. In spite of several organizations in our city and State which are caring for tuberculous invalids, the number of the latter is so great that many urgent cases are suffering from lack of proper climatic treatment. In New York State alone during the year 1899 thirteen thousand persons died from tuberculosis, and the report of the State board of health for that year shows an increase of three hundred deaths from this disease

over the year preceding. Since tuberculosis has been classed as a contagious malady, patients suffering therefrom are not received at our city hospitals, excepting in cases of a very few institutions which have special tuberculosis wards. During the year 1900 ten thousand cases were reported to our medical health board, and it is estimated that at the present time in New York City alone there are thirty thousand cases." The proposed Stony Wolde Sanatorium will be non-sectarian, and the medical board by which it is to be conducted is composed of physicians of the highest standing in New York and Albany.

Honors for Sir William MacCormac.—His Majesty the King of Italy has promoted Sir William MacCormac to the degree of grand officer of the Order of the Crown of that country.

Death of an Eminent Foreign Professor.—Joseph Fodor, M.D., professor of hygiene at the University of Budapest, has recently died. He was born in 1843, studied under Pettenkofer at Munich, and later under Baron Liebig. Dr. Fodor was, after his master Pettenkofer, the best known of the European sanitarians, and did much toward rendering Budapest the healthy and beautiful city it now is. He was a man of many gifts, and was for some time joint editor of the medical journal *Orvosi Hetilap*.

Adulteration of Food.—Dr. Wiley, chief chemist in the department of agriculture, recently delivered an address on the above subject before the Westchester Woman's Club of Mount Vernon. He drew attention to the somewhat anomalous fact that while various States have laws forbidding the adulteration of foods, there is no national law regulating the matter, so that food which is adulterated in New York State can be taken to New Jersey and sold, the law prohibiting the sale of it in the State of New York. Some adulterations are harmful, while others are not; among the harmless list being the adulteration of coffee with peas, beans, chicory, etc. Samples of the various substances used to adulterate coffee were exhibited, and the statement was made that ninety-six per cent. of all the coffee that comes into the United States is from Brazil. Dr. Wiley referred to the manufactured wines, showing samples of port, sherry, and claret that were entirely innocent of the juice of the grape, and pieces of silk dyed different colors by these spurious wines. He further spoke of the adulteration of milk, butter, and spices, and other articles, the lecture being illustrated by specimens of various foods and their adulteration.

New Tuberculosis Cure Announced.—A multitude of cures for tuberculosis have been heralded from time to time with a loud flourish of trumpets, but all as yet have proved, in the words of the preacher, "vanity and vexation of spirit." So much has this been the case that whenever one hears now of another remarkable cure for consumption one is apt to be sceptical as to its true value. The latest remedy brought forward is in its way unique. Dr. Henry Harper, an English physician, it is reported, has been experimenting with urea, hypodermically injected, with wonderfully successful results. Dr. Harper noted the fact that, in spite of the beneficial effects of fresh air in the treatment of consumption, many of his patients came from the country, and further, that while the carnivora were comparatively exempt from the disease the herbivora were peculiarly liable to contract it. Again, his investigations showed him that gouty or rheumatic families were seldom the subjects of tuberculosis, while those who were especially prone were, as a rule, large vegetable and fruit consumers. He found that there were recorded several instances in which a severe attack of gout had either checked or cured cases of tuberculosis. The common belief is that gout and rheumatism are owing to an undue production of urea and uric acid in the system, which condition is aggravated by meat eating. Therefore, Dr. Harper argued that the presence of these constituents in the blood is antagonistic to the germ of tuberculosis. Acting on this assumption, he procured urea and began to use it in scruple doses four times a day on a consumptive patient. The treatment was begun on June 28, 1899, and continued with gradually increasing doses up to September 19th, when the patient was, to all intents and purposes, cured. So encouraging a result warranted a more extended trial of urea, and it is said that the same treatment has been pursued in nine other cases of indisputable tuberculosis, effecting a complete cure in some and great improvement in most of the others.

X-Rays without Electricity.—A cable to the New York *Sun*, April 2d, reports that it was announced on April 1st at a sitting of the Academy of Sciences that M. Curie, a chemist, had separated a new gas from rhodium. The gas is intensely phosphorescent, and will glow for months in the dark. It was also announced that M. Naudon, a scientist, had found means of producing *x*-rays without electricity, by exposing a metal plate to the rays of the violet end of the spectrum.

Smallpox and Vaccination in Paris.—*La Presse Médicale* has an interesting article by Dr. Roger on the above subject. Dr. Roger is in charge of the Isolation Hospital wards at Aubervilliers, and, in the article referred to, explains why smallpox lingers so long in Paris. He says that the continued prevalence of the disease is mainly due to laxness in carrying out vaccination and to faulty methods of performing the same. Dr. Roger concludes by saying: "The lamentable state of things, therefore, in Paris is that we know how to suppress smallpox, but we do not put our knowledge into effect. Compulsory vaccination and revaccination and an effective isolation of the infected —*ibi salus est*."

Objection of Hawaiians to Segregation and Vaccination.—The segregation of lepers and compulsory vaccination are looked upon by many Hawaiians as acts oppressive, especially to people of their race. While none of their representatives has as yet dared to come out squarely against segregation, a number of bills have been introduced to modify the law on the subject, and several bills have been introduced which

aim in one form or another at repealing the vaccination law. A largely signed petition was presented in the house of legislature for the repeal of certain sections of the laws for the segregation of lepers, the repeal of the compulsory vaccination laws, and the passage of a law to "license Hawaiians to practise medicine." The meaning of the last clause is to license what are called *kahunas;* that is, persons claiming occult power by means of old Hawaiian enchantments and ceremonials, to cure disease, to pray enemies to death, and generally to bring good or ill fortune. *Kahunas* exist at the present day and wield a great influence over the Hawaiians, but their practices are forbidden by law. A considerable number of deaths among Hawaiians are attributed by the Hawaiians themselves to the supernatural power of *kahunas*, and in some cases are undoubtedly due to the fear felt for their mysterious power.—*New York Evening Post.*

New Knights of St. John of Jerusalem.—Among the new Knights of Grace of the Order of the Hospital of St. John of Jerusalem in England will be found Mr. Frederick Treves, Mr. A. D. Fripp, and Colonel G. S. Ryerson, M.D., their appointments being in recognition of their services tc the British troops in South Africa. Earl Roberts is also appointed to the order, as are the Duke of Portland, Mr. Langman, Mr. Alfred Moseley, and Mr. Van Alen, of New York.—*The Lancet.*

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting held April 8th, Dr. H. A. Hare exhibited "An Interesting Case of Aneurism." The patient was an old colored man, with generalized arteriosclerosis, who presented a pulsatile, expansile swelling in the course of the right carotid artery above the level of the clavicle, in addition to various valvular murmurs. The suggestion was made that the vascular condition was not one of aneurism, but rather one of extreme compensatory tortuosity of a diseased artery. Dr. J. A. Scott exhibited "A Case of Endocarditis Resulting from Typhoid Fever." The patient was a young man in whom in the course of a mild attack of typhoid fever leucocytosis developed, and on further careful observation a mitral systolic murmur appeared, which grew progressively more intense with the passage of time and became attended with enlargement of the heart to the left and downward. Dr. A. O. J. Kelly read the report of "A Patient with Marked Enlargement of the Liver and Spleen," without anæmia or leucocytosis, or glandular enlargement, or a history of syphilis or of malarial fever or of a cause for amyloid disease. Dr. S. McC. Hamill read the report of "A Case of Aneurism of Thirteen Years' Standing Recently Operated on for the Removal of a Huge Cyst of the Broad Ligament." The aneurism was situated upon the arch of the aorta, and the operation was undertaken only upon the urgent demand of the patient after the dangers and the possibilities of the situation had been explained. Dr. Joseph Sailer reported "A Case of Aortic Regurgitation with Flint Murmur." There were audible during life systolic, diastolic, and presystolic murmurs, while after death the mitral leaflets and orifice were found perfectly free, and the aortic leaflets and orifice were the seat of disease. Dr. D. J. Milton Miller exhibited "Specimens Showing Thrombosis of the Right Innominate, External and Internal Jugular, and Axillary Veins from a Case of Aortic and Mitral Disease."

"Rudolf Virchow Fund."—To the American Medical Profession: On October 13, 1901, Rudolf Virchow will be eighty years old. When he completed his seventieth year a fund was started in his honor to enable the great master to facilitate scientific research by establishing scholarships, and by encouraging special medical and biological studies. Contributions to that "Rudolf Virchow Fund" were furnished by those in all countries interested in progressive medicine, as a homage to the man whose name is always certain to arouse admiration and enthusiasm. In Berlin a large committee containing among others the names of A. Bastian, v. Coler, A. Entenburg, B. Fraenkel, O. Israel, Fr. Koenig, C. Posner, and W. Waldeyer has been formed to call for contributions which are to be added to the original "Rudolf Virchow Fund" so as to increase its efficiency. The committee expresses the opinion that in no better way, and in none more agreeable to the great leader of modern medicine, can his eightieth birthday be celebrated, and ask for the sympathy and co-operation of all those engaged in the study and practice of scientific medicine all over the globe. The undersigned have formed a sub-committee for the purpose of making the American profession acquainted with the intentions of the Berlin committee, and urge their colleagues to participate in honoring the very man who has done more, these fifty years, than any other to make medicine a science, and international. Subscriptions should be sent to their secretary, who will receipt therefor. Charles A. L. Reed, president of the American Medical Association; Henry P. Bowditch, president of the Congress of American Physicians and Surgeons; William K. Welch, Johns Hopkins University; Robert F. Weir, president of the New York Academy of Medicine; A. Jacobi, 110 West 34th Street, New York, secretary.

House of Mercy Hospital at Pittsfield.—An extensive hospital is shortly to be erected in Pittsfield by the House of Mercy. The projected building, as is fitting in an institution of this kind, is not to be distinguished by its external architectural adornments and decorations, but will be rather striking by its severe and plain simplicity. The hospital will have a 198-foot front and a depth of 50 feet, and will be built of red brick laid in white mortar, with sandstone trimmings. The hospital is to be constructed on the block principle, with a central building three stories high, and north and south wings two stories in height. The three sections will contain eye and ear department, ambulance department, and maternity department, and will be thoroughly equipped with all modern appliances. There will be fifty-two patients' rooms. The building will be semi-fireproof and stand back from the street thirty feet. A feature in the construc-

tion will be the fact that the maternity department is so situated that there is seclusion for the patients, and other patients are not subjected to the disturbance of "infants crying in the night."

Pennsylvania Society for the Prevention of Tuberculosis.—At the annual meeting, April 10th, Dr. Guy Hinsdale was elected *President*, and Dr. Alexander Heron Davisson *Secretary*.

Woman's Medical College.—The sum of $500 for five years has been guaranteed by the Alumnæ Association of the Woman's Medical College for a European fellowship for study abroad, to be awarded to applicants in the near future.

The Pennsylvania Hospital, which has been designated "the mother of American hospitals," will celebrate on May 11th the one hundred and fiftieth anniversary of its organization, and arrangements are being made for an appropriate observance of the occasion. The petition for the founding of the hospital was written by Benjamin Franklin, and was presented to the assembly of the province of Pennsylvania, January 23, 1751. The bill was after some difficulty passed by the general assembly May 7, 1751, and on May 11th received the approval of Lieut.-Gov. James Hamilton. On February 6, 1752, after sufficient money had been collected, a mansion in the city of Philadelphia was rented for the purposes of the hospital. The cornerstone of the first structure at present occupied was laid May 28, 1755, with Masonic rites, and the building was opened on December 17, 1756. Since then there have been gradual additions to the hospital, until today it is one of the best-equipped institutions in the world.

Acting Assistant Surgeon, Marine-Hospital Service.—The United States civil-service commission announces that on May 7, 1901, an examination will be held in any city in the United States where postal free delivery has been established, for the position of acting assistant surgeon in the Marine-Hospital service. The examination will consist of the following subjects: 1, letter writing; 2, anatomy and physiology; 3, surgery and surgical pathology; 4, chemistry, materia medica, and therapeutics; 5, bacteriology and hygiene; 6, theory and practice of medicine and general pathology; 7, obstetrics and gynæcology. Age limit, twenty years or over. From the eligibles resulting from this examination it is expected that certification will be made to the position of acting assistant surgeon in the Marine-Hospital service, at Portland, Me., at a salary of $600 per annum, and to other similar vacancies as they shall occur. This examination is open to all citizens of the United States who comply with the requirements and desire to enter the service. All such persons are invited to apply, and applicants will be examined, graded, and certified with entire impartiality and wholly without regard to any consideration save their ability as shown by the grade attained in the examination. Preference may be given to eligibles who are residents of the district in which the vacancy exists. Persons who desire to compete should at once apply to the United States civil-service commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and promptly forwarded to the commission.

Dr. Mazÿck P. Ravenel, of the University of Pennsylvania, Philadelphia, should be the gentleman credited in a recent issue with the work of tubercle dissemination by cows, and not Dr. Mazyck, as stated.

Philadelphia County Medical Society.—At a stated meeting held April 10th, Dr. Jay F. Schamberg exhibited "A Case of Dermographism" in an adult male, who applied for treatment for pruritus. Wherever the skin was irritated there appeared, after transitory pallor, flushing followed by elevation, with diffusion of the injection and then gradual pallor and fading. These phenomena are due to primary contraction of the cutaneous vessels, followed by their dilatation and the escape of serum, and at times also blood-cells. The condition is allied to urticaria, angioneurotic œdema, and other disorders comprehended in the term vasomotor ataxia. It is known also as factitious urticaria. Dr. J. Madison Taylor presented the "Report of the Committee on the Pay Hospital for Contagious Diseases," in which he recited the progress being made in the achievement of the desired object, and for which the continued support and encouragement of both the medical profession and the community were necessary and solicited. Dr. John B. Roberts read a paper entitled "The Doctor's Fee—a Plea for Honorable Dealing." He contended that while the fee of the physician should be ample in accordance with the skill and authority of the individual, it should not be extortionate, and that the standard should be the maximum the service is worth, and from which concessions could be made in accordance with the conditions present in the individuals. The practices of giving and accepting commissions, of any division of fees between consultant and attendant, of writing testimonials for secret medical preparations, and of the practice of corporations, such as insurance companies, in endeavoring to secure confidential information from physicians concerning patients without the knowledge or sanction of the latter, were unqualifiedly condemned.

Association of American Medical Colleges.—The next regular meeting of this association will be held at the Hotel Ryan, St. Paul, Minn., Monday, June 3, 1901. It will consist of two sessions, an educational and a business one. The educational session will be opened at 2 P.M. by the president's address, followed by several papers of medical pedagogic interest. To this session all persons interested in medical education are respectfully invited. The representatives and associates of the Association of Southern Medical Colleges have received a special invitation. The members of the Confederation of State Examining and Licensing Boards are also invited. There will also be an exhibition of work done in medical colleges. At 8 P.M. the business session will be held, at which the amendments to the constitution, proposed by several colleges, will be considered. The report of the judicial council, the election of

members, and the election of officers for the succeeding year will close the programme. Albert R. Baker, M.D. (Cleveland, O.), *president;* Bayard Holmes, M.D. (Chicago), *secretary*.

Doctor Shot in the Foot.—Dr. Benson, of Guttenburg, N. J., was stopped early on Thursday morning, April 11th, by a man who threatened him with a pistol. The doctor struck the pistol from the man's hand, when it discharged, a bullet passing through the doctor's foot. After wrestling for a few minutes, the footpad succeeded in getting away.

Michigan Plague Case.—Charles B. Hare, the Ann Arbor student supposed to be suffering from bubonic plague, is on the road to recovery. Dr. Novy, the University of Michigan professor and one of the experts despatched by the government to San Francisco to investigate the plague situation there, says with regard to Mr. Hare's case: "Nothing has yet been decided, but he is recovering rapidly. He will be kept isolated until next week, or until it is certain he cannot spread infection."

To Regulate the Speed of Automobiles.—The senate committee of New York State on internal affairs has decided to report favorably Assemblyman Doughty's bill regulating the speed of automobiles in cities and incorporated villages to eight miles an hour and fifteen miles an hour outside of cities and villages. The bill was thus amended so as to give the park department in New York City power to regulate the speed of such vehicles upon park roads, streets, and avenues under its jurisdiction, while in the rest of the State local authorities may determine whether these vehicles may run faster than the minimum prescribed.

Children's Home at Albany Attacked by Smallpox.—The Lathrop Memorial Home, an institution located in the heart of Albany, is the scene of an outbreak of smallpox on a large scale. The home is mainly an orphanage, and is supported by Mrs. Leland Stanford. About thirty-two children are inmates of the home, nearly all being more or less stricken with the disease. One or two of the children who had been vaccinated have escaped infection, and only one of the attendant teachers has contracted smallpox of a mild nature. The disease is said to have been present for two weeks, but, the cases being mild, the attendants mistook it for chickenpox, and a physician was not called in at once. The local health board has quarantined the home.

Christian Science and Religion.—Clergymen of various denominations are decrying the principles of Christian Science, some of the ministers declaring that its tenets are not only entirely incompatible with true Christianity, but that it is the most subtle means of undermining Christian beliefs that has yet appeared. It can scarcely, however, be hoped that declaiming against this peculiar fad will have the effect of bringing the followers of Mrs. Eddy to reason. On the contrary, judging from the experience of the past, persecution, or apparent persecution, has ever tended to arouse the sympathy of the general public in favor of those attacked. To make martyrs is the surest way to strengthen and consolidate a belief, bizarre as it may be. Indifference is the most certain method of killing fads.

Woman Sanitary Inspector.—At the meeting of the Woman's Club of Orange on April 11th, an appropriation of $500 was made toward the salary of a woman sanitary inspector of Orange for a year, the woman to be appointed by the board of health on nomination by the joint committees of the women's clubs of the Oranges.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ended April 13, 1901. Medical Director W. K. Scofield detached from special duty at Philadelphia, April 27th, and ordered home to wait orders. Medical Director W. G. Farwell detached from the Philadelphia navy yard and ordered to duty in Philadelphia, special. Surgeon C. Biddle ordered to the Philadelphia navy yard, April 27th, as relief of Dr. Farwell. Surgeon S. H. Griffith ordered to duty at the Pan-American Exposition, Buffalo, April 25th, in charge of the exhibit of the Bureau of Medicine and Surgery, Navy Department. Assistant Surgeon R. B. Williams detached from the Pensacola navy yard and ordered to the Key West naval station, with temporary duty at Dry Tortugas. Medical Inspector J. R. Waggener detached from the naval hospital, Cavite, and ordered to the Mare Island hospital, having been condemned by a medical board of survey.

Much Sickness at Canton.—Robert M. McWade, United States consul at Canton, says the New York *Tribune*, reports ten thousand deaths from plague to have occurred there in the past six weeks, and that there are thirteen cases of smallpox on the United States monitor *Monterey*. Only one death has resulted on the *Monterey*, and the other cases of smallpox are doing well.

Leprosy in the Canaries.—United States Consul Berliner, writing from Teneriffe, says: "Leprosy is somewhat endemic among people here, on account of their eating a good deal of fish, often putrid, and their general uncleanliness. As to being contagious, the theory is generally discredited here, but, in my opinion, it is very infectious."

Smallpox in Foundling Hospital.—An outbreak of smallpox has been reported in the Foundling Hospital at Sixty-eighth Street and Lexington Avenue. There are about two hundred and fifty children in the institution, most of whom have been vaccinated recently. Inspectors of the board of health have been engaged in vaccinating all the others, and the managers of the hospital have thoroughly disinfected the building. As a result of these precautions it is not anticipated that the disease will make headway.

Accident to a Hospital in Japan.—A terrible fatality is reported from Tokio, where the hospital of the medical department of the university—a wooden structure—was destroyed by fire. No less than twenty-one patients lost their lives, and ten nurses and patients were seriously injured.

Plague Increases in Cape Town.—Plague in Cape Town is on the increase. On March 31st the total number of cases was two hundred and eighty-seven and the deaths numbered ninety-nine. It is also reported that a physician in attendance on plague cases has contracted the disease while performing a necropsy on a victim. The doctor is said to have had an abrasion of the skin on his hand, and to have become infected by this means.

Marriage Control in Indiana.—The Indiana legislature has passed a bill providing for the appointment of a marriage commission, to be composed of two women who are mothers, two physicians of note, and one attorney. The duties of the commission are to prepare a set of questions which it is proposed to require candidates for marriage licenses to answer, the idea being to prevent marriages between the unfit.

Wedding of a Physician which Cost Thirty Thousand Miles' Travel.—The Sunday *Sun*, March 24th, has this clipping from the *Evening Wisconsin*. Dr. Henry M. Bridgman, Cape Town, South Africa, and Miss Florence R. Jones, of the Argentine Republic, formerly teacher in the Racine High School, were married recently in Racine. The newly wedded pair will leave for Kimberley, South Africa, their future home, and when they arrive there, they will have travelled nearly thirty thousand miles to be married. The bride-elect was giving private instruction to a family of children in the Argentine Republic when she first met Dr. Bridgeman, and he soon after went to Cape Town and began practice, and when the engagement was announced Miss Jones travelled alone to Racine and the doctor came on from South Africa.

Typhoid in New Haven.—Owing to the prevalence of typhoid fever in New Haven the precaution has been taken to boil all the water to be drunk in schools.

Obituary Notes.—Dr. Frank Abbott, the well-known oculist, died in Buffalo on April 9th after a long illness. Dr. Abbott was oculist-in-chief at the General Hospital and the Eye, Ear and Throat Hospital of Erie County.

Dr. William J. Youmans, aged sixty-three years, died at Mount Vernon on April 10th. Up to a year ago he was editor of *The Popular Science Monthly*. His native place was Saratoga, and he graduated in medicine from New York University in 1865. After studying in England under Huxley, he returned to America and commenced to practise in Minnesota, but after three years abandoned it to join his brother in establishing *The Popular Science Monthly*. Dr. Youmans was well versed in chemistry, metallurgy, and physiology, and wrote upon these subjects for "Appleton's Cyclopædia." He also edited Huxley's "Lessons in Elementary Physiology."

Dr. William F. McClelland died at Denver, Col., on April 12th. Dr. McClelland, who had an international reputation as a successful and daring surgeon, was one of the first to recognize and make public the good effects of climatic influences of the mountain regions upon pulmonary diseases. The deceased physician was eighty years of age at the time of his death.

Progress of Medical Science.

New York Medical Journal, April 13, 1901.

A Shielded Piston Syringe for Urethral and Vesical Irrigation.—By J. R. Eastman. The objection to most of the instruments in present use is that being constructed on the fountain-syringe principle they are difficult to sterilize, may allow of gravitation to the bottom of the reservoir of small crystals of permanganate which may irritate the tissues, do not allow of an instantaneous shutting off of the current, make it difficult to gauge the pressure, and require considerable time for their preparation and employment. The author has devised an instrument which he describes as follows: It consists of a five-ounce metallic piston syringe with detachable blunt nozzles. A thin-spun metal shield surrounds the barrel. The shield is made movable, in order that it may be held up while the nozzle is introduced into a graduate or other vessel for filling. The syringe being filled, the shield is pushed down along the barrel and fastened by a slot-and-pin catch about an inch behind the tip of the nozzle. The advantages claimed are: (1) It is easily and entirely sterilizable. (2) The solution is taken from the top of a column of liquid, as, for example, in a large graduate, and crystals that may be present in the bottom of the receptacle are not taken up. (3) With the piston syringe the pressure exerted may be finely gauged by the resistance against the operator's thumb pressing the piston. (4) The force of the current may instantaneously be lessened or the stream entirely cut off. (5) The use of the instrument is attended with no inconvenience or loss of time. (6) It is easily transportable. (7) It is simple in construction and application.

The Preponderance of Male Stammerers Over Females.—By David Greene. Out of 256 stammerers, 229 of whom were males and 27 females, the author found the following conditions: Number of cases of stammering caused by faulty inspiration, males 139, females 3; by faulty expiration. (*a*) mismanagement of the voice, males 25, females 20; (*b*) defective articulation, males 8, females 0; (*c*) mismanagement of the voice and defective articulation, males 57, females 4. The reason assigned for the preponderance of male stammerers over females is the fact that in the male subject ordinary, quiet respiration for vital purposes is effected almost exclusively by the activity of the diaphragm; but, in speaking, a more considerable emptying of the quantity of air in the lungs must take place, and this can be effected only through the combined processes of diaphragmatic and costal breathing. In females, costal breathing is the habitual mode of respiration, hence their lungs are generally well supplied with the quantity of air which is necessary for speaking purposes, and cases of stammering caused by deficient inspiration are very rare among them.

The Correction of Deviations of the Nasal Septum with Special Reference to the Use of the Author's Fenestrated Comminuting Forceps.—By J. O. Roe. The paper is accompanied by several illustrations showing the various deformities of the intranasal structures, and the author claims for his well-known method of operation many advantages. He states that the superiority of the fenestrated over flat-bladed forceps for breaking up the base of the fragments at their bony attachments is apparent and that the former also obviates bringing strain on the septum and disturbing its upper attachments, thus opening the way for brain complications. Moreover, it completely removes the elasticity of the attachments of the deflected parts, facilitates the ready adjustment of the septum to its normal position, and diminishes to a minimum the length of time a support to the septum is required.

German Text Books Half a Century Ago; History and Reminiscences.—By A. Jacobi. Address delivered at the New York Academy of Medicine on the occasion of the celebration of the author's fiftieth anniversary of graduation in medicine.

The Pathology of Intra-Uterine Death.—By Neil McPhatter.

The Management of Gonorrhœa.—By B. Lapowski.

Medical News, April 13, 1901.

The Immediate and Remote Results in One Hundred Conservative Operations on the Ovaries and Tubes; with Brief Reports of Four Cases.—W. L. Burrage in his discussion of this subject states that it is his belief that, in order to arrive at just conclusions concerning these cases, they must be under observation for at least a year after operation. Out of 100 cases, symptomatic cure was recorded in 73, while 27 were not relieved. These figures must not be unduly emphasized, since a large number of the patients were pronounced neurasthenics, in which cases there is great difficulty in determining the relative causative effect

of disease of the uterine organs and disease of the nervous system on the symptoms presented in a given case. Anatomical cure (ovaries and tubes normal to feel and well placed) was noted in 44 out of 69 cases who came under observation—sixty-four per cent. Some enlargement or prolapse of ovaries and tubes was found in the remaining 25 cases. Pregnancy following operation occurred in 19 cases. In no instance, however, did pregnancy result after the resection of a closed tube, both tubes being closed at the time of operation. In order to estimate the probability of pregnancy occurring after conservative operations on the ovaries and tubes, all patients who are by any means barred from pregnancy, *e.g.*, those who take measures to prevent conception, widows, etc., should be eliminated from the list. Under these circumstances, 32.7 per cent. became pregnant. It may be stated that 34.5 per cent. of those who had previously borne children became pregnant after operation, whereas only 6¼ per cent. of those previously sterile subsequently became pregnant. The amount of ovarian tissue present seems to have no definite relation to the amount of menstrual flow or to the intensity of sexual desire and gratification. The author believes the most unfavorable cases for conservative operations are those of pronounced neurasthenics who are approaching the menopause, also patients with long-standing gonorrhœal infection, and those having both ovaries thoroughly riddled with cysts. The author classes as conservative operations all those in which, an operation on the appendages being performed, not including cases of hysterectomy or suspension of the ovaries, one ovary, a portion of one ovary, or one tube or a portion of one tube was left behind.

Perforating Gunshot Wound of the Chest with Fracture of Both Bones of the Left Leg and Lacerated Wound of the Right Thigh; Recovery.—Victor Cox Pedersen reports the case of a man aged thirty-one years, who through irregular habits of life and long strain became hyperneurasthenic. On the morning of December 11, 1899, in a state of nervous excitement, he shot himself through the left chest; finding this effort in vain he jumped out of a third-story window. He was admitted to the hospital at 7:35 A.M. in a state of profound shock, with active delirium, flaccid abdomen, and the left chest less active than the right. He had received ♏ ix. Magendie's solution when first seen by the ambulance surgeon, and ♏ v. more in the reception ward, with atropine sulphate gr. $\frac{1}{100}$, strychnine sulphate gr. $\frac{1}{20}$, and a stimulating enema of whiskey. The wound of entrance was at the fifth space, three and one-half inches out; the wound of exit at the eleventh space, four and one-half inches out, on the left side. There were indefinite signs of fluid in the infra-scapular and infra-axillary regions. The heart was acting well. The abdomen was slightly rigid, but not distended. Simple complete Pott's fracture was present at the left ankle. There was a large lacerated wound in the right thigh almost reaching the bone, and nearly admitting the hand in its cavity. The gunshot wounds were covered with 1:5,000 wet bichloride dressing; the laceration was irrigated, packed, and covered with the same. The fracture was left in the temporary ambulance dressings. Operative interference was contraindicated by the general condition. The patient was kept absolutely quiet with morphine. His abdomen was rigid, distended, tender, and tympanitic. Perforation of the stomach was suspected. The Magendie solution was continued. On the third day the general condition was much better. A Volkmann splint was applied to the leg. The thigh wound was packed with iodoform gauze in bichloride solution. The diagnosis of gastric perforation was abandoned. On the fifth day the signs of peritonitis were disappearing. The management of the pistol-shot wound was daily changes of the wet dressings, followed by dry sterile dressings and aristol powder. Neither wound suppurated. The laceration was treated in the usual way. The fracture united in good position and with full function after the ordinary plaster splint. Skin grafts were used on the thigh wound. The patient was discharged May 8, 1900, cured. The forced quiet through sedatives, morphine, etc., appears to have saved his life.

A Study of Cases Presenting Symptoms of Asthenopia and Anomalies of the Ocular Muscles in which Ablation of the Middle Turbinal was Effective Treatment.—By Heber Nelson Hoople.

Tropacocaine Hydrochlorate: a Substitute for Cocaine Hydrochlorate in Spinal Anæsthesia.—By Willy Meyer.

The Akouphone and its Limitations.—By J. A. Kenefick.

Acute Traumatic Malignancy.—By William B. Coley.

The Boston Medical and Surgical Jour., April 11, 1901.

Oblique Subtrochanteric Osteotomy for the Lengthening of the Femur, and Correction of the Deformity of Flexion Resulting from Hip-Joint Disease.—E. G. Abbott describes his operation, which differs from that of the German savants by obviating the use of too powerful force in the separation of the bone and the destruction of much tissue subcutaneously, thereby reducing the liability to infection and injury to the blood-vessels and nerves. The points to which the author especially calls attention are: (1) The importance of making a radiograph, which enables one to determine the size of the femur, and the exact location at which the osteotome should be entered in order to free the attachment of the iliopsoas muscle to the trochanter minor. (2) The width of the osteotome must be regulated by the size of the bone, so as to secure a clean-cut surface by one passage of the instrument. The angle at which it is held must also be governed by the size of the femur.

A Case of Chin Left Posterior.—H. J. Swain reports a case in which successful delivery was obtained by first making gentle pressure of the head, so that it was placed above the brim between an assistant's hands holding it through the abdominal walls. As a foot could be easily felt, it was brought down, the assistant at the same time turning the head up. Delivery was easy as a half breech. The commonly accepted mechanism was impossible in this case, because, while the head was so far down that it could advance no farther without violence, the chin was not impinging against anything.

Pathology of the New-Born as Illustrated in the Practice of the Writer.—Frederic W. Taylor reports that out of 654 obstetrical cases in his pratice, 64 of the children were abnormal either at birth or during the first few days of life. Of infants stillborn there were 23; children dying within a few days, 22; children whose respiration was delayed, 10; deformities, 2; ophthalmia, 3; melena, 2; depression in the skull, 1; facial paralysis, 1. The author gives details of the various abnormalities.

A Review of the Literature of the Therapeutic Use of the X-Rays.—By Harvey P. Jowle.

The Jour. of the Amer. Medical Ass'n, April 13, 1901.

Reflections upon the Recent Status of Clinical Medicine.—Aloysius O. J. Kelly believes that medicine is the art of healing disease; and that it is founded upon various sciences. A knowledge of pathology is necessary to the physician. The results of the cultivation of the scientific spirit are obvious in all departments of medicine, but nowhere more conspicuously than in the field of etiology. The science of bacteriology has added infinitely to our store of knowledge and has been of incalculable benefit to humanity. The diagnosis of disease is and always will remain an art, but it is becoming more and more scientific. It is now known that in the majority of cases bacteria produce their injurious effects by reason of the poisons they elaborate. The exact nature of these poisons offers a fertile field for investigation. In the selective action of these toxins we find a rational explanation of many of the phenomena of the different diseases. The establishment of the doctrine of internal secretions is another result of the cultivation of the scientific spirit in medicine. Upon the doctrine of the bacterial origin of disease are founded the modern conception and practice of sanitary science. With regard to therapeutics and practical care of disease, it is certain that the scientific researches of recent years have taught us much. Serum therapy may be regarded as the crowning glory of the cultivation of the scientific spirit of the nineteenth century.

Immunity from Zymotic Diseases.—William J. Class concludes that in districts where a certain zymotic disease is endemic the germs of this disease are comparatively widely distributed, although in a very much attenuated form. Epidemics are due to these germs becoming virulent either by repeated passage through the animal body, or in some other manner not as yet known. It is only after attaining a certain degree of virulency that they are capable of producing a typical attack in a susceptible person. Immunity from or insusceptibility to a given zymotic disease is usually acquired through the activity of the attenuated germ, which, although not capable of producing a typical attack, is still capable of producing an antitoxic body. The presence of pathogenic bacteria in the normal body, described as a "latent infection" by Adami and others, is in accord with the theory formulated. These bacteria are probably an attenuated species, and their office is a beneficial one, as, through their activity, the animal organism is probably saved from a severe infection.

A Visit to "Jesus Hilfe," or the Leper Hospital at Jerusalem.—Jacob E. Schadle speaks of the origin and growth of the hospital, of its management and inmates, of leprosy in Palestine, and of leprosy investigations. He then discusses the clinical features of this dread disease and its treatment. There are numerous illustrations with descriptions. As to the communication of leprosy, he relates an instance of how it was conveyed through eggs. A leper lying in the sand of his yard threw the exfoliations from his body to the hens. The eggs of these hens were sold to a family, a member of which contracted the disease. The

author then compares leprosy and tuberculosis. The bacilli of the two diseases are strikingly alike. The distribution of the two kinds of bacilli in the tissues is very different, those of tuberculosis generally being arranged singly, while the lepra bacilli are always in large quantities in masses and clumps.

What Drug Standardization Means for the Physician.—A. R. L. Dohme states that drug standardization means that drugs shall always be uniform in therapeutic strength, which offers to the physician the advantage of always obtaining definite and uniform therapeutic effects in prescribing a standardized drug. It removes all element of doubt from the physician's mind.

The Present Status of Spinal Surgery.—Samuel Lloyd gives an extensive table of cases of Pott's paraplegia which have been operated on. The article is to be continued.

Ligation of the Carotid Artery as an Operation Preliminary to Resection of the Superior Maxilla.—Carl Schlatter summarizes the observations obtained from his resections of the superior maxilla and from a study of the literature as follows: (1) By the application of a preliminary ligature the hemorrhage, as well as the danger from blood aspiration, is markedly diminished. (2) This ligation is highly recommendable in all anæmic individuals, and in those whose vitality has been lowered from cachexia and hemorrhages, provided they do not suffer from diseases of the blood-vessels, particularly arteriosclerosis. Exposing the bifurcation of the carotid in advanced cases is in itself indicated for the purpose of extirpating the lymphatic glands, which in this region are generally the first attacked by metastasis. (3) In by far the most cases ligation of the external carotid alone will suffice; the latter should be a permanent ligation. Conducted aseptically, the procedure is without danger. The ligature can be applied by enlarging above the incision which has been made for exposing the bifurcation. (4) In exceptional cases it becomes imperative to ligate the common carotid, which, if done temporarily, seems to be less dangerous than a permanent ligation. The author states that the limitations of this operation are greater in actual practice than at first appears.

Multiple Tumors of the Sciatic Nerve.—John B. Roberts reports the case of a man aged thirty-nine years, who fourteen years ago had first noticed three small tumors about the size of peas on the outside of the left leg near the knee. They were excised. For the last fourteen years the patient suffered with pain in the left popliteal region. About five years ago he felt a lump deep in the left popliteal space. Pain was continuous. On incision the sciatic nerve and its internal and external popliteal branches were found to be involved. About thirty-six growths were removed. There was practically no pain after the operation, and the wound healed by first intention. The tumors were fibromas. No marked numbness of the foot remained, and on the patient's discharge he had good motion in all the toes.

Thoughts on the Treatment of Diabetes Mellitus, being Part of a Clinical Lecture Delivered at the Philadelphia Hospital, March 13, 1901.—By James Tyson.

Ruptured Traumatic Aneurism of the Femoral Artery due to Gunshot Wound; with Report of a Case.—By Wallace Neff.

The Amer. Journal of the Medical Sciences, April, 1901.

Enteroptosis.—James R. Arneill declares that one dislocation, such as gastroptosis or nephroptosis, is usually but a manifestation of enteroptosis. Symptoms and anatomical signs on the part of one organ, however, may predominate. Enteroptosis is a disease of great importance to the general practitioner, for it is endemic the world over, and he is generally the first to be consulted by sufferers from it. These are cases which every day are being diagnosed as neurasthenia, spinal anæmia, nervous exhaustion, nervous dyspepsia, and change of life. It is easy to learn how to recognize an enteroptotic. She is slender, poorly nourished, pale, tired, neurasthenic in appearance, dragging about, and entirely lacking in vivacity and energy. The author then describes methods of examination, calling attention to Stiller's phenomenon—the costal stigma or floating tenth rib. The symptomatology is very varied. In many patients, nervous symptoms predominate. They complain frequently of palpitation of the heart and forcible pulsation in the abdominal aorta. Again, there are striking symptoms on the part of the stomach and kidneys. Many have uterine displacements. There is in many a congenital predisposition to this disease. Frequent childbearing, straining at stool, etc., are causes. Surgical treatment is indicated in some cases; in others, abdominal bandages or belts with properly applied pads may relieve symptoms. However, there must be a great deal of individualizing in the treatment of this condition.

Multiple Neuritis and Hæmatoporphyrinuria following the Prolonged Ingestion of Trional.—Stuart Hart observes that patients readily acquire the trional habit, which is difficult to break. He then reports the case of a woman aged fifty years, for whom trional had been prescribed. The whole amount ingested was not excessive—about thirty doses of gr. xv. each, a total of gr. cmx. for two months. The onset presented the picture of acute gastro-intestinal poisoning. After this there were an acute degeneration of the kidneys and the presence in the urine of hæmatoporphyrin. The first nervous manifestation was a neuritis of the vagus and a subsequent trophic disturbance in the heart muscle resulting in dilatation and valvular insufficiency which cleared up with the improvement in the muscular tone. There were extreme emaciation and a marked thickening of the tissues about the joints of the fingers. The urinary change appeared some time after the development of the nervous symptoms and a considerable period after the withholding of the drug.

Primary Splenomegaly.—By N. E. Brill.

British Medical Journal, April 6, 1901.

Placenta Prævia.—R. P. Ranken Lyle states that the diagnosis of this affection is not difficult, and depends on the fact of the placenta being felt to be attached to the lower uterine segment. The prognosis as regards the mother depends on the variety of placenta prævia; on the treatment adopted, any form of mechanical dilatation of the cervix or the rapid extraction of the child being extremely dangerous to the mother; on the amount of interference; on early treatment. The prognosis on behalf of the child depends on the period of pregnancy, the amount of hemorrhage, and the rapidity of labor. Generally, the best treatment for the mother is the worst for the child. As to treatment, the conditions which should guide one are: complete or incomplete placenta prævia, the nature of the presentation, whether labor be absent or present, the character of the pains and the size of the os uteri, and whether the membranes are ruptured or not. The author then gives the advantages of version: it does away with the tampon and consequent danger of infection; it allows early operation; it arrests the hemorrhage with great certainty; it gives time for the patient to rally; it gives time for labor pains to set in and consequent natural dilatation of the cervix to occur; there is less danger of post-partum hemorrhage.

On a Uterus which Contained One Hundred and Twenty Fibroids.—J. Bland-Sutton reports this very rare case. He removed this organ by the abdominal route, leaving both ovaries and Fallopian tubes. The uterus had a peculiar oval shape and measured 10 cm. in the vertical and 15 cm. in the transverse axis. There were four sessile fibroids projecting into the cavity of the uterus. These tumors were about the size of pigeons eggs. After the uterus was carefully hardened in methylated spirit, it was found to contain a multitude of fibroids, varying in size from a coriander seed to a cherry stone. The uterus itself was about the size of a fist. From the microscopical examination the structure of these tumors was observed to be that of a plain muscle tissue with alternate and whorled disposition of the spindles. The minute fibroids were strikingly like the large, fully developed fibroid. Each was globular and on section quite white. Each was sharply differentiated

from the uterine tissue by a thin capsule from which it could be enucleated. This specimen is certainly unique.

Note on Epilepsy and Heart Stoppage.—R. G. Hebb states that while he was listening to the heart of a patient suffering from aortic regurgitant disease, the heart suddenly stopped beating, and almost simultaneously he felt great pressure on the stethoscope. The patient was stiff and rigid, and was at once laid on the floor, when a general convulsion, intense though of short duration, occurred. The patient was quite unconscious; the lips were blue; there was no frothing at the mouth. In a few minutes it was all over and the patient sat up. He answered questions coherently and lucidly, and got up directly without the least difficulty. He was twenty-nine years of age and had had two similar attacks before. In none was there any warning or aura. In 1897 he had rheumatic fever.

Large Salivary Calculus without Symptoms; Spontaneous Extrusion.—George J. Maguire reports the case of a man aged forty-five years, who for four years had had a salivary calculus which never even caused a passing feeling of discomfort and certainly none of the pain usually incident to this affection. One day the patient noticed a small white spot on the floor of the mouth which felt hard and gritty on touching it with a needle. A few minutes later, while eating a meal, a large hard mass was suddenly, with some force extruded. The calculus was large, white, and ovoid, and weighed forty-five grains.

A Case of Spontaneous Version.—James J. O'Donnell, on examining a patient in labor, found the body of the fœtus in the abdomino-anterior position. He endeavored to turn the child, but being unable to do so without an anæsthetic, went to his own home to procure it. On his return he found the legs of the child protruding, but the head was above the brim. The child was extracted and the mother made a normal recovery.

A Case in which a Large Pyloric Tumor Disappeared after Gastro-Enterostomy.—By F. B. Jessett. The case is worthy of record as it is one in which a tumor of the size of a small cocoanut completely occluding the pylorus, and having all the naked-eye appearances of a carcinomatous growth, disappeared after operation; also because of the length of time the patient lived after the operation in perfect comfort, namely, ten years, being at the time of death sixty-six years of age. Special points of interest in the case are the following: (1) At the time of operation the tumor had all the macroscopical appearances of a case of carcinoma of the pylorus causing obstruction. At the necropsy the pylorus was found to be patent, although somewhat constricted, the mucous membrane covering it being apparently quite healthy; the pyloric orifice was situated immediately behind the constriction, which undoubtedly represented the seat of the tumor, so that possibly the tumor being in this position by its size blocked the pylorus which apparently was not implicated in the growth, and as the growth became atrophied and the obstruction removed the opening again became available for the passage of food. (2) It is most remarkable that this growth should have so completely disappeared, leaving only a small contracted cicatrix adherent to the liver to indicate its position. There had never been any vomiting of blood or other indications to account for its disappearance. Indeed, the tumor was quite prominent and had been demonstrated on several occasions after the operation up to within about two years of the patient's death when only a slight thickening could be detected. (3) Although evidently food had passed by the pylorus, yet the opening between the stomach and jejunum formed the main channel for the passage of food from the stomach into the intestine. The communication between the proximal and distal pouches of the stomach formed by the contraction and cicatrization at the seat of the tumor was very narrow, barely admitting the index finger, and it is difficult to understand why the patient did not suffer more inconvenience than she did from the passage of food from the one pouch to the other.

Diseases and Disorders of the Heart and Arteries in Middle and Advanced Life.—Third Lettsomian lecture by J. Mitchell Bruce. This lecture is devoted principally to prognosis and treatment and the writer passes in review the different therapeutic plans which are current. The great indication is the maintenance of compensation. The nutrition and activity of the myocardium can be increased and sustained by means of specific cardiac stimulants and tonics, such as strychnine, ammonia, and the digitalis group of drugs, with hæmatinics, stomachics, and laxatives to insure an abundant supply of wholesome blood, by the control of nervous influences—one of the conditions of healthy nutrition—and by the employment of the non-medical measures now so extensively used to increase the vigor and benefit the metabolism of the cardiac walls, particularly active and passive exercises and baths. When true failure of compensation ensues, as manifested by residual dilatation of the heart, mechanical congestion, and dropsy, the following rules may be carried out: First, we must not be afraid to purge these patients, if necessary every morning. Secondly, when the appetite flags and flatulence occurs, instead of slops a blue pill or dose of calomel should be given and light solids persevered with. Thirdly, nocturnal restlessness and sleeplessness are to be met unhesitatingly with permission to spend the night in an easy chair by the bedside. Fourthly, according to the author's experience, acupuncture and drainage succeed perfectly in these senile cases with dropsy, as much as ten pints or more of serum escaping in the course of twenty-four hours, to the complete and often lasting relief of the circulation.

On the Existence of Immunity after Typhoid Fever.—By B. A. Nicol. Contrary to the generally accepted belief that an attack of enteric fever confers some degree of immunity upon the patient against further attacks of the same disease, the author feels that this conclusion is based upon very flimsy evidence and gives certain histories which bear out his views. He is of the opinion that at present there is no proof existing of the presence of an immunity after an attack of enteric fever. Immunity varies much in different diseases and in different individuals; erysipelas leaves behind it apparently a predisposition to further attacks; diphtheria and pneumonia as far as we know give no protection; while an attack of one of the exanthemata usually protects its subjects very effectually. What place enteric fever is to take in this respect has still to be determined. The author's recent clinical experiences have led him to doubt the existence of any immunity in many cases. A large number of men in the present African campaign have, however, quite escaped the onslaughts of enteric fever, and it is reasonable to think that all must frequently have been exposed to the risks of infection. If we can discover the reason for their resistance to the disease, we may then hope to discover some method of general protection. Statistics may show that inoculation is a step in the right direction, but meanwhile we should not forget that the teachings of sanitary science to-day point out clearly many paths along which efforts at prevention can be successfully made.

Pathology and Treatment of Rheumatoid Arthritis.—P. W. Latham thinks that the clinical symptoms in this disease furnish undoubted evidence of pathological change in the nervous centres, the exact nature of which can be determined only by further microscopical investigations. In the earlier stages of the disease he thinks that continuous counter-irritation of the spine is of distinct service, and that it may also be usefully employed in the acute polyarticular variety. But when the disease is advanced, the ends of the bones are enlarged, and the cartilages are destroyed, one cannot hope to restore these to the normal condition by any counter-irritation. Such a measure would only increase the patient's discomfort. Nevertheless, in chronic cases, in which there are from time to time exacerbations of pain and swelling in some of the larger joints, the application of blisters to the spine is of use; and Latham has seen these conditions very quickly alleviated thereby and the further extension of the disease arrested.

Sclerotic Hyperplasia of the Pharynx and Naso-Pharynx.—By A. Brown Kelly. The author discusses the history of a case to which he gives the designation noted in the title. He concludes by saying that (1) the pharynx and naso-pharynx may be the seat of a sclerotic hyperplasia unconnected with syphilis, rhinoscleroma, or other known infective disease; (2) that a similar morbid process may

manifest itself beneath the vocal cords as subglottic hypertrophic laryngitis; and (3) that in the hyperplastic variety of hereditary syphilis the histological appearances closely resemble those of the above-described sclerotic hyperplasia.

Berliner klinische Wochenschrift, No. 12, March 25, 1901.

A Case of Pneumo-pyopericardium.—By R. Sievers. The patient was a domestic aged thirty-two years, who when coming under observation presented evidences of old syphilitic infection and of present left-sided croupous pneumonia which had become gangrenous. The heart appeared normal. Some six weeks from the commencement of the pulmonary trouble examination revealed an absence of cardiac dulness and the appearance over the heart region of a metallic tinkle evidencing the presence of air and fluid in the pericardium. Death occurred four days later. The autopsy showed the pericardium considerably dilated and both layers covered with a purulent deposit. Section of the sac caused the forcible escape of a quantity of gas with a hissing sound. A communication was found existing between the sac and the collection of pus in the pleural cavity, and between the latter and a broken-down area in the lung tissue.

The Operative Treatment of Varices and Varicose Phlebitis.—By Dr. Karewski. This paper is a review of the various surgical procedures which have been suggested for the condition and a strong plea for excision of the affected vessels.

Progress of Investigation of Malaria in Italy.—By M. Koch and Coenen (concluding article).

The Prognosis of Brain Diseases in Childhood.—A continued article by H. Oppenheim.

Münchener med. Wochenschrift, March 19, 1901.

The Therapeutic Value of Heroin and Aspirin.—A. Nusch is a warm advocate of the first-named drug and considers it safer for general use than morphine, codeine, and dionine, the range between the therapeutic and toxic doses being much greater than it is for these preparations. Some observers place the upper limit of dosage at gr. $\frac{1}{50}$, but in the author's opinion up to gr. $\frac{1}{6}$ can be used with impunity. It is particularly as a sedative in the cough of phthisis that heroin surpasses other remedies of like nature; in dyspnœa of mild degree it is often useful, while in severe cases its action is but slight. As an analgesic its value is still *sub judice*, and whatever hypnotic powers it may possess are probably due to its sedative effect in relieving the cough and bronchial irritation. Aspirin (acetyl-ester of salicylic acid) has an extensive field of utility, and is of value not only as antirheumatic but also has antineuralgic, analgesic, and antipyretic powers. It possesses the active properties of the salicylates without producing any of their disagreeable by-effects, and may be used as a wholly equivalent substitute for these.

The Technique of Lorenz's Bloodless Operation for the Reposition of Congenital Dislocation of the Hip.—Schlesinger says that the enormous degree of force often necessary to effect reduction of the deformity by this method frequently results in serious accidents, such as fractures of the femur, injury of the perineum or genitals, pressure on the femoral vessels, etc., and describes a simple procedure by which the difficulties of the operation can be greatly diminished and all risks eliminated. After, by gentle manipulation, an attempt at reposition has been made, one assistant fixes the pelvis with both hands while another forcibly holds the limb in the position from which reduction takes place. A firm plaster-of-Paris dressing is now applied and allowed to remain three to four days, when it is removed and manipulation again tried. In most cases it will be found that reposition can be effected with the greatest ease (in one case reported it took place spontaneously in the dressing), while if difficulty is still encountered a repetition of the treatment insures success.

The Protargol Treatment of Gonorrhœa.—Niessen has treated two hundred and forty-four cases of acute gonorrhœa with one-half to three-quarter-per-cent. injections of protargol, and arrives at the following conclusions: Both silver nitrate and protargol in acute cases of infection of the anterior urethra cause the gonococcus to disappear from the secretion at about the same time, viz., the end of the third week. In solutions of the above-named strength no disagreeable symptoms were produced by protargol; the effect of stronger solutions was not tried. Even though it is not possible in all cases to prevent the progress of the process backward into the posterior urethra, protargol seems to insure greater freedom from complications than the nitrate, while in the mucous and serous stages, when no gonococci are present, astringents are to be preferred. Although protargol presents certain undoubted advantages, on the whole its use does not reduce the duration of treatment below that necessary with the best of the older methods.

The Treatment of Leg Ulcers.—O. Schultze recommends camphor as a cheap and easily applied substitute for the more expensive modern dusting-powders. An ointment having lard as a base and containing two per cent. of camphor with fifteen to twenty per cent. of zinc oxide is of great value; if this seems impracticable, zinc oxide may be added to an equal weight of four-per-cent. camphor solution in olive oil and the mixture applied on compresses.

A Further Case of Intestinal Obstruction Treated with Atropine.—W. Höchtlen was unsuccessful in the atropine treatment of his case and the patient succumbed, the cause of the obstruction being found to lie in massive adhesions about the junction of the ascending and transverse colon.

The Atropine Treatment of Intestinal Obstruction.—In Simon's case operation was averted and recovery brought about by the subcutaneous use of large doses of atropine.

The Treatment of Tuberculosis with Intravenous Injections of Hetol.—By A. Kühn.

Experimental Observations on Hand Disinfection.—By Paul and Sarwey.

Max von Pettenkofer.—By K. B. Lehmann.

Deutsche med. Wochenschrift, March 21, 1901.

The Surgical Treatment of Gastric Ulcer and its Sequelæ.—W. Körte reports on thirty-eight cases of operation for benign disease of the pylorus and its neighborhood, including thirty-two cases of stenosis following or accompanied by ulceration. In numerous instances the thickening was massive, simulating a malignant new growth, and while in most cases the hydrochloric acid was increased it was absent or diminished in seven of the number. The chief indications for operation were stenosis and secondary dilatation, though sixteen cases of perforation, and one of dangerous hemorrhage, are included in the list. Resection, gastro-enterostomy, pyloroplasty, and gastrotomy were tried, the conclusion being that gastro-enterostomy is the most generally useful procedure. Direct suture was done, the Murphy button being dispensed with. Resection is a suitable treatment for many cases, and is especially indicated when carcinoma is suspected, but it demands favorable conditions with absence of adhesions and greatly taxes the recuperative powers of the patient. The deaths reported were due in two cases to collapse, in two more to secondary bleeding from the ulcer, and in one each to pneumonia, pericarditis, and suppuration.

The Indifferent Dye Stuffs as Fat Stains.—L. Michaelis believes that in "Scarlet R" histologists and pathologists will find a satisfactory substitute for the osmic acid and Soudan iii. in general use as staining agents for fat. Chemically this substance is toluolazotoluolazo and naphthol, and possesses the advantage over osmic acid of staining every fat, and fat only. The myelin sheaths in the fresh or degenerated state, as well as the lipochrome of ganglion cells, can be clearly differentiated, the best combination for use being a saturated solution in seventy-per-cent. alcohol.

An Observation on the Demonstration of a Pirogoff Stump by Solger.—Kern comments on this demonstration by a description of two stumps which represented a period of use after operation of two months and three years respectively. Sections of the bones showed internal structural changes due to the altered conditions of stress which were undoubtedly progressive, since they were much more radical in the older preparation than in the recent one.

Experimental Observations on the Compensation of Sensory Ataxia.—By A. Bickel.

The Alleged Immunity of the Hedgehog to Cantharides.—By L. Lewin.

Trigeminal Disease as a Forerunner of Tabes.—By v. Fragstein.

Bulletin of the Johns Hopkins Hospital, February, 1901.

Two Examples of Bence Jones' Albumosuria Associated with Multiple Myeloma.—Louis P. Hamburger reports this case. The patient was a woman aged forty-nine years. In August, 1900, she was seized with sharp pain over the ninth left rib near the cartilaginous attachment. The pain was severe and increased on deep inspiration. There was

tenderness on pressure over the painful point. The condition resembled a fracture, though there was no history of trauma. Within three weeks the pain had gone. In September she complained of nausea without apparent cause. Her general health was worse; she had lost thirteen pounds in weight. Early in October she was seized again with pain in the mid-axillary line near the eighth rib. At this time the urinary condition was discovered. Since the past summer the patient had drunk more water than usual, and had voided a larger quantity of urine. On November 3d, excepting a slight pallor of the mucous membranes, physical examination was negative. The urine was very pale, of an acid reaction, with specific gravity of 1.004. It gave a white ring when floated over nitric acid. Heated to a temperature of about 55°, a heavy milk-white precipitate appeared. Boiled, the fluid became clearer, only to become more turbid on cooling. The addition of acetic acid to the fluid after reaching its maximum turbidity caused it to become clear again. A few drops of nitric acid yielded a precipitate which dissolved completely on boiling and reappeared on cooling. In the Esbach albuminometer the proteid content reached 0.27 per cent. The urine gave a strong biuret reaction. No casts were seen in a centrifugalized specimen. This, then, is a condition of albumosuria which is an accompaniment of sarcomatosis of the bone, of a very peculiar variety, originating in the marrow and known as myelomata, new growths affecting for the most part the skeleton of the trunk. The exact nature of the substance giving rise to the reactions of Bence Jones has not been determined. The origin of the proteid is as obscure as its character. The urine usually contains traces of albumin. As to myeloma it does not originate in the marrow cells as a whole, but in the plasma cell only. This disease is one belonging to later life and runs its course generally within two years.

Report of a Case of Fulminating Hemorrhagic Infection due to an Organism of the Bacillus-Mucosus-Capsulatus Group.—George Blumer and Arthur T. Laird report a case in which the intestinal tract was in all probability the primary seat of infection. The patient, a man aged twenty years, had been in perfect health and working till October 19, 1900. He went to work that morning as usual after a hearty breakfast, but returned just after noon. He went directly to bed complaining of feeling ill. He had pain in the abdomen, vomited, and purged, his bowels moving every few minutes. After twelve hours the vomiting had practically ceased, the bowels moved only once in about four hours, the temperature was subnormal, the hands and feet were cold and cyanosed, and the face looked pinched. At the end of twenty-four hours the mind was confused and the patient had completely collapsed. Death occurred at the end of thirty-six hours, there having been at no time the slightest tendency toward recovery. The case is of interest pathologically on account of the proliferative changes in the intestinal lymphatic apparatus discovered at autopsy. The solitary follicles throughout the small intestine were markedly swollen and, in the ileum, Peyer's patches were also affected. The mucosa of the intestine between the swollen lymphatic apparatus was congested and in places markedly hemorrhagic, in places the Peyer's patches contained discrete hemorrhages. The large intestine was normal. The mesenteric glands were swollen, some of them being pale, others hemorrhagic.

Abstract of Interim Report on Yellow Fever by the Yellow-Fever Commission of the Liverpool School of Tropical Medicine.—By Herbert E. Durham and the late Walter Myers.

Hyperextension as an Essential in the Correction of the Deformity of Pott's Disease, with the Presentation of Original Methods.—By R. Tunstall Taylor.

Preliminary Note of a Case of Infection with Balantidium Coli (Stein).—By Richard P. Strong and W. E. Musgrave.

Introductory Note to Drs. Durham and Myer's Report.—By William H. Welch.

The Edinburgh Medical Journal, April, 1901.

Osteomalacia.—W. E. Fothergill gives the following rules for the management of this disease: (1) In men and in non-pregnant women, internal medication should always be patiently tried, together with hygienic and dietetic precautions. In women, if the disease continues to progress, double oöphorectomy may be performed and followed up by continued medication. (2) In early pregnancy abortion may be induced and treatment continued as above. If a living child is specially desired and the symptoms are slight, pregnancy may be allowed to continue, medical treatment being kept up throughout. (3) In late pregnancy it is necessary to decide whether or not a living child can be born at term *per vias naturales*. If not, a choice must be made between the induction of premature labor and a pre-arranged Cæsarean section, as embryulcia should not be contemplated. (4) During labor, the child, if living, must be delivered alive by the method indicated by the circumstances of the case. If the abdomen is opened, the ovaries are removed, whether the uterus is also removed or not. Embryulcia is permissible only when the child is dead. Medical treatment must be continued after the operation, as relapses frequently occur.

Pernicious Anæmia; with an Analysis of Eighty-seven Published Cases, and an Inquiry into the After-History of Twenty-two Reported Cures.—Horace C. Colman considers that in the treatment of pernicious anæmia the most success may be hoped for from rest in bed, farinaceous diet, the use of some intestinal antiseptic and mouth wash, and, above all, from arsenic in increasing doses, and, after some improvement has been shown, from the additional and cautious use of iron. Should the arsenic fail, then recourse must be had to phosphorus and bone marrow. In very advanced cases temporary benefit may result from transfusion. Lastly, should a favorable result ensue from the use of arsenic, the patient should continue that drug for a very long period, even though feeling in perfect health.

On the Diagnosis of Thoracic and Cardiac Aneurism by the Roentgen Rays.—Hugh Walsham considers it the duty of the physician to make use of this method of examination in all doubtful cases of chest disease, especially if an aneurism be suspected. He describes the apparatus to be used and the method of applying it to obtain satisfactory results, and reports five cases in which the *x*-rays established a diagnosis which could not be made from the physical signs. He adds that the danger of dermatitis has been obviated by the introduction of the large coils now in use, which enable one to make an exposure so short that no injury can be done. In an experience of over five years he has never seen any injury arise from the exposure necessary for obtaining a skiagram of the chest.

Remarks on Two Cases of Enteric Fever, Complicated with Rigors and Exacerbations of High Temperature.—By Vincent Dickinson.

Light and Color Perception.—By F. W. Elbridge-Green.

The Scottish Medical and Surgical Journal, April, 1901.

Notes on the Treatment of Diseases of the Nervous System.—J. J. Graham Brown gives a detailed lecture on the treatment of paralysis resulting from lesion of the upper motor neuron. In cases of apoplexy he says that if the diagnosis is certain and if there are signs of a continuing hemorrhage, and if the site of the lesion is the usual one, it may be advisable to compress the carotid artery in order to diminish the rate of the circulation, and so allow of clotting and the arrest of hemorrhage. It may even be well to ligature that vessel in special cases. The quickest and most effectual way of reducing the intracranial tension is by blood-letting. But a clear and certain diagnosis of cerebral hemorrhage must be made, for in the case of embolism or thrombosis venesection would be very harmful. The cases in which it is likely to do good are those in which the face is darkly flushed, the pulse slow and full, and the coma deep and of long duration.

Uterine Retraction with Special Reference to the Mechanism and Management of the Third Stage of Labor.—D. Berry Hart sums up his views as follows: (1) The Porro uterus is an over-retracted uterus and does not indicate the normal amount of retraction of the third-stage uterus. (2) The "intact uterus" is not so markedly retracted as the Porro uterus at the site of the unseparated placenta, and gives a more reliable indication of the amount of retraction under normal third-stage conditions. (3) Retraction of the uterus is most marked in the parturient uterus where the membranes are attached, above the site of uterine rupture, and in the post-partum uterus, the attachment of placenta and membranes hinders full retraction. (4) The placenta is separated in the third stage during the elastic recoil of the uterus following a pain, and not during a pain. (5) No uterine pressure can directly separate the placenta with safety.

A Case of Erythema Multiforme, Closely Resembling Smallpox.—Norman Walker reports a case occurring during a smallpox "scare." The eruption on the face, neck, and back did not resemble smallpox, but on the hands the likeness was marked. The history of the case was altogether against such a diagnosis. The patient had been vaccinated two weeks before and a large scab testified to the efficacy of the inoculation. She had had no rigor, no dorsal pain, nor sickness, and the temperature was subnormal. After consideration and consultation with the health authorities, the diagnosis of smallpox was negatived, and the after-history of the case showed that the physicians were correct.

OUR LONDON LETTER.

(From Our Special Correspondent.)

WEATHER AND PUBLIC HEALTH—PARLIAMENTARY PURE WATER AND PURE BEER—THE DEBATE ON TYPHOID IN SOUTH AFRICA—A DISCUSSION ON RHEUMATIC AFFECTIONS—NATIONAL HOSPITAL—DEFENCE OF MR. COUTTS.

LONDON, March 29, 1901.

THE weather has forced itself to the front even in this time of political and social excitement. Snow, blizzard, tempest, frost, pipes burst, and plumbers—such have been the subjects of conversation, but you will have learned of the most severe visitations by cable, and as we have a sudden change this afternoon with rain we take courage. The effect on the public health must be injurious. Many of the more noted men have been prostrated. Influenza is rife. Whooping-cough, too, has greatly increased.

The vigorous measures taken to cope with smallpox in Glasgow are beginning to bear fruit. The epidemic, it is hoped, is subsiding, as there are fewer cases, and the same news comes from surrounding districts.

A case of plague was brought to Southampton on a steamer. It was at once transferred to the isolation hospital ship and other measures were taken to prevent the spread of the disease.

In parliament the government has had some rebuffs which interest sanitarians, and there are not wanting many who think it has been shaken by these, as it unquestionably has been by the easy terms it has offered the Boers. On Tuesday four hours in the house of commons were devoted to the water bill of the county council. Ultimately it was rejected by a majority of only seventy-seven—a significant fall from one hundred and fifty. In 1880 London water wrecked a government. This year a new county council is returned with a mandate to brook no longer delay, and the government opposes with a promise to bring in a bill next year—a dangerous move. Next day pure beer took the place of pure water, and after a whole afternoon's debate the second reading was carried by one hundred and twelve majority. It is said the bill will not get through the remaining stages. The government seems afraid of the beer interests. It is even said they will not facilitate the bill to keep children from the public house, though the second reading was carried by a magnificent non-party vote.

The adjourned debate on typhoid among the troops in South Africa was resumed last Friday. The president, Sir Douglas Powell, referred to Dr. Howard's communication to the Washington Academy of Science on the part played by flies He also mentioned the question of water conveyance and Lord Dundonald's newly invented water cart, a model of which was on view at the meeting.

Sir William Broadbent thought possibly we might have to revise our ideas as to typhoid being always conveyed in this country by water, directly or indirectly. With the troops, he remarked, there were predisposing causes, as debility, overwork, underfeeding, as well as gastro-intestinal catarrh and digestive troubles. He held it proved that diarrhœa and dysentery favored the origin of typhoid. The effect of a mixed infection might be more serious than that of the bacillus. He asked whether Europeans took typhoid to Africa or found it there? What was its incidence on the natives? Was the fever in South Africa the same as ours?

Sir William Church repeated what he said on a former occasion in defence of the commission, denying that they had hurried over their inquiry, though they had worked very hard to prevent delay. They met on the day of arrival and carried on their investigations for thirty-five days without excepting Sundays. He then passed on to the clinical aspects of the disease, which were of course not within the scope of the commission's duty. He was inclined to think inoculation had a modifying power, and he had often observed that it was imperfectly performed. He thought the chief source of infection was Paardeburg, where the river was full of dead horses and the British camp below that of the Boers. Experiments show that the bacilli live a short time in dry sterile sand, but as much as two hundred and forty days in soil, but it is not yet decided whether they sporulate or not—and spores might remain indefinitely. It was safe to assume they would live some time in dry dust, and this might explain cases in lone farms when there had been no communication with towns or other houses for weeks. Sand storms might play a part in conveying the disease. On the march the clouds of dust must have been immense. Flies were another danger. Sir William said flies so congregated round the typhoid patients that you could tell which were suffering from it as you entered a tent hospital.

The type of the disease among the troops seemed specially virulent. Many soldiers stuck to duty after the onset and thus contributed to the extension. The thirst under the hot sun was intolerable and it was not to be wondered at that the soldiers were injudicious in quenching it at any risk. It was often difficult to obtain fuel to boil the water. The Modder water sometimes resembled pea-soup and would clog any filter. He did not know why more Abyssinian wells were not sunk. Typhoid had always prevailed in armies since its distinction from typhus. Sir William thought that a sanitary medical officer should be attached to every camp, as was formerly the case.

Dr. A. Crombie gave statistics of one hundred and fifty consecutive cases of convalescence from the South African epidemic. They showed unusual frequency of second attacks, numerous cases of thrombosis and mucocolitis. The rash was reported to be profuse and in many cases to have extended over the whole body. These South African cases thus contrasted strongly with a form he had called bastard typhoid, common in India, running a mild course without rash, diarrhœa, complications, or sequelæ. The South African cases indicated either special virulence of the bacillus—a supposition negatived by the low mortality—or else a mixed infection. This latter view was supported by recent experiments and observations which pointed to the necessity of reconsidering whether the varying clinical picture called "enteric" might not be the result of such mixed infection.

Captain W. A. Ward, R.A.M.C., was convinced that flies played a prominent part in Ladysmith; the food was covered with them in masses. In one spot he found an enteric camp had existed some years ago. It could not be realized at home what difficulties they had to contend with. The clinical picture differed from that in England; the advent was sudden, the pain in the head very acute, and the rash peculiar, appearing on the sixth to eighth day, very profuse but with no relation to the severity of the attack. The temperature was often intermittent. The disposal of the dead was a difficulty. Places where typhoid patients had been buried would form future foci, and he was in favor of cremation. The question of inoculation must be treated with caution. Personally he was inclined to think that the inoculated men had milder attacks and less mortality.

Dr. A. P. Hillier remarked that in the tropics there were a number of unclassified fevers, called simple continued fever. In Kimberley, where he practised for seven years, typhoid recurred every summer and autumn, and the water supply was above suspicion. He thought dust conveyed the disease more often than water. Filtering and boiling he did not think made water safe. He would appoint more than one sanitary officer and supplement the army medical corps with physicians.

Dr. Horton-Smith pointed out the danger of the urine and the possibility of neutralizing it by urotropin.

Dr. Arthur Longhurst said there were not many types of typhoid, but in hot climates it was more severe and fulminating. He thought the bacillus might remain dormant in the system as the malarial microbe did. Typhoid was better treated in a tent than in hospital.

Dr. Tooth, in reply, said there was room not only for a sanitary officer, but a corps. Professor Wright had said the dose of inoculation should be adjusted to the patient, but he did not see how. He confirmed the statement that typhoid cases could be picked out by the flies around them. Some of the simple continued fevers were exhaustion, some a fever *sui generis*, but the majority mild typhoid; seventy-five per cent. gave the Widal reaction. Urotropin was not adapted for ambulant cases.

What is rheumatism? This question might very well produce such a sensation as that of the historical "what is a pound?" To many the word rheumatism or rheumatic is a sort of charm. Its utterance satisfies them that is something they understand—a pain they put down to cold and damp, referring it to the weather. We have succeeded in considerably contracting the number of cases to which the term rheumatism has been attached and in differentiating others in which it remains; but there is still no little confusion, even in the profession, owing to the indefinite way in which the term is employed. It is therefore not surprising that the public should rest satisfied with a word which includes so many aches and pains, and explain them as due to such ever-present causes as chill and weather. In view of these many questions connected with the word a discussion of them can scarcely be devoid of interest, and such a discussion has occupied two evenings at the Chelsea Clinical Society. It was opened on the 12th inst. by Dr. Archibald Garrod, who would limit the term rheumatism to rheumatic fever and its chronic sequelæ, or at any rate to conditions depending on the same morbid process. He said few would deny that acute rheumatism is an infective disease—a systemic malady in which joints and heart are both apt to suffer and which may implicate the skin, nervous system, and other struc-

tures. The process may smoulder on for years, and its manifestations are exceedingly numerous and various. The precise terms for discussion set forth were "the clinical and pathological relations of the chronic rheumatic and rheumatoid affections to acute infective rheumatism." Dr. Garrod addressed himself to the question thus set and expressed the opinion that three, if not more, forms of articular disease are included under the terms "rheumatoid" or "osteo-arthritis." He related cases of the fusiform, nodular, and crippling forms, contrasting the three with each other and with the senile hip-joint affection. He referred to the various points which had led some to look upon rheumatoid arthritis as a continuation of acute articular disease and stated that in the majority of cases it appeared to him to be a primary malady.

Dr. F. J. Poynton then read a joint paper by himself and Dr. Alexander Paine on the Infectivity of Acute Rheumatism, with especial reference to chronic types of the disease. They regard acute disease as due to one specific organism, and look upon pericarditis, pleurisy, and nodules as manifestations of the disease. From fourteen cases of rheumatic fever they have isolated a diplococcus which grows in streptococcal chains in liquid media; in staphylococcal masses on solid media. Though further researches may be desirable, they believe the organism to be the cause of the disease. In some cases malignant endocarditis is truly rheumatic and this is suggestive as to the nature of some joint lesions which run on to ulceration and destruction of cartilage.

Mr. N. C. Macnamara admitted that some cases of rheumatoid arthritis are attributable to gout, others to rheumatism or a neurosis, and held that others depend on toxic substances produced by organisms. Like Dr. Todd, he had seen cases which he attributed to the absorption of septic matter—as from the uterus or the sockets of the teeth in extensive caries. The cure for such cases would be the removal of the cause of the septic matter.

Dr. C. O. Hawthorne marshalled the several theories as to rheumatoid arthritis and the points for and against each. He seemed to favor most the idea of change in the trophic nervous apparatus or else the idea of rheumatism, but did not definitely adopt either. Loath to commit himself to the theory of a neurosis, he was not prepared, he said, to go so far as to say he held very strongly that rheumatoid arthritis was certainly rheumatism. When so much was vague and uncertain, he thought it was no reproach to halt between two opinions. The debate was adjourned at this point.

On Saturday last the Lord Chancellor presided over a meeting of the governors of the National Hospital for the Paralyzed and Epileptic which ended in a complete climb-down of the committee. More than two hundred supporters of the hospital were present, and a resolution was moved on behalf of the committee to the effect that an inquiry into the allegations of the staff ought to precede their demand for representation. An amendment was at once brought forward, and eventually carried, that a full and independent inquiry be at once instituted. It is significant that this inquiry is ordered to include "the position, functions, and acts of the secretary-director." This is the anomalous official whose proceedings have, I believe, brought on the trouble, and, as I told you when last alluding to the matter, ought to be dismissed. The choice lies between him and the eighteen distinguished members of the staff. He has written that the "hospital may encounter worse evils than the resignation of the staff," but no one outside the board he controls seems to agree with him. That board should also be displaced by the governors as unfit for the position it holds.

A voice has been raised within the profession in favor of Mr. Burdett-Coutts. *The Medical Press and Circular* accepts that gentleman at his own valuation—perhaps at a higher one. His excellent qualities are described in a leader, and among them, to the amazement of many, accuracy is included, notwithstanding the contradictions he has had to endure. The commission is referred to as appointed "to deal with one side of the question and to report favorably upon the army medical service." This service is said to have been "reponsible for the breakdown" and the defence to have been "entrusted to the incriminated department"—two unsupported charges which have been again and again disproved. According to this leading article, Mr. Coutts "has riddled through and through the commission and all its works," and it is pronounced, in the elegant terms of his speech in the House, as "the weakest and rottenest basis of reform." What can have happened to *The Press and Circular?* It used to be well informed on army questions.

In Insomnia try a hot bath at bed-time. In aged subjects give very small but frequently repeated doses of hyoscyamus.

OUR PARIS LETTER.

(From our Special Correspondent.)

MINERAL WATERS IN FRANCE. THEIR AMELIORATION—PRACTICAL SURGICAL INSTRUCTION IN THE PARIS FACULTY OF MEDICINE—CHAULMOOGRA OIL IN LEPROSY—WASHING OUT THE STOMACH IN GASTRORRHAGIA—TRINITROL AS A CARDIAC DRUG.

PARIS, March 23, 1901.

THE American medical men who were present at the Thirteenth International Medical Congress remember very likely having received a book on "The Mineral Waters in France," setting forth their special advantages, and indicating in what manner they were to be employed for the cure of different ailments. The number of watering-places in France is certainly very large, and perhaps no country in the world offers so great a variety of springs furnishing different kinds of mineralized water, with different conditions of heat, quantity of mineral subtances and gases. The chief trouble, however, and it is one that French physicians are aware of, is that no special pains are taken to bring before the international medical public the merits of such waters. Such is far from being the case in Germany, where the waters are extensively advertised; everything is done to attract foreigners, such as having hotels that afford a special cuisine, different amusements, the laying out of walks, and a certain cosmopolitan character in the place itself.

The book given to the members of the congress was destined to enlighten them in some measure, just as the yearly trips undertaken under the direction of Professor Landouzy are a means of giving practical instruction to the French physicians as well as to foreigners.

This question has been taken up seriously recently by a member of the chamber of deputies, M. d'Estournelles de Constant, who is getting up a series of lectures in different parts of France, on the natural advantages of the country where they are given. In a letter published in the *Temps*, the great French journal of conservative tendencies, M. d'Estournelles writes in the following manner: "In those regions where there are to be found not only mineral springs and special climatic conditions, but also the picturesque and historical sites sought after by patients, we shall try to make the inhabitants of the region understand that it is by our own initiative that we can attract travellers and thereby increase the profits of railway companies, hotel keepers, farmers, etc. We will try to show how France can be lifted up, rendered more prosperous and strong by organizing, transforming the public hygiene, and understanding her own true interests."

It will therefore be well for physicians to furnish those who are to speak on these different subjects, statistics and figures which will be of great help to them.

The general secretary of the *Presse Médicale*, M. de Lavarenne, has written recently some articles on the lack of surgical training shown by the average graduate from the school of medicine. According to this author, a great number of young doctors do not know how to handle a knife, and would be incapable of performing such simple operations as a kelotomy or even the opening of a simple abscess. Until recently the practical instruction given at the school of medicine consisted in showing the student how to find an artery or how to cut off a limb. Such operations are certainly of some importance, but are much less required than the different operations so often performed in ordinary practice. It was felt necessary to give the student some chance of learning something more about certain more complicated operations, such as the removal of a kidney, or a laparotomy. Dr. Tuffier, whose name is about as much heard as Doyen's, has started at the Collège de France a series of practical demonstrations, in which both professor and pupil operate on dogs which are placed under the influence of a narcotic. This new attempt has been advertised by means of posters placed on different public buildings, and it cannot but help to attract the attention of the public.

In answer to these articles by de Lavarenne, Dr. Hartmann, former assistant of Terrier, has written a letter in which he upbraids de Lavarenne with having neglected to speak of the courses which are given under his direction at the École Pratique of the Faculty of Medicine. Dr. Hartmann is helped by several prosectors or demonstrators, who choose different sections of surgical science, and perform the different types of operations before the students. These courses are not, however, gratuitous like those usually given at the Faculty of Medicine, and the average student does not care to make the extra outlay in time and money so as to acquire a sufficient knowledge of the operations which he will be called upon to perform later.

At the meeting of the Academy of Medicine, which took place on the 5th of March, several interesting communications were made by different members. Dr. Hallopeau read a report on a work by Dr. Tourtoulis concerning the treatment of leprosy by subcutaneous injections of chaul-

moogra oil. The author had obtained fairly good results and persistent amelioration. Dr. Hallopeau remarked that chaulmoogra such as is obtained in the hospitals of Paris is often adulterated, so that the results achieved are often quite variable.

Subcutaneous injections of oil are not always without ill effects, so much so that he has decided to give the oil by the mouth in doses of gtt. cc. to ccc. daily. Before believing that the remedy is the sole agent in the recovery it should be remembered that leprosy sometimes improves spontaneously. Dr. Ducastel said he considered chaulmoogra oil might have some effect in cases of tubercular leprosy, but that in nervous leprosy it gave no result. This treatment should be used exceptionally, in serious cases, as it was painful and dangerous and might sometimes cause pulmonary embolus.

Dr. Linossier advocated treating gastrorrhagia by washing out the stomach. He spoke of two cases in which the vomiting of blood could not be stopped and in which he obtained good results. Dr. Bondet said he washed out the stomach in ulcus simplex with a weak solution of perchloride of iron, and was favorably impressed by the treatment.

Professor Huchard has tried a new drug, called trinitrol, which he employs instead of amyl nitrite and trinitrin, the latter being not so lasting in their effects. Trinitrol, or tetranitrate of erythrol, is given in doses of 1 cgm. Six doses may be given in one day.

OUR CONSTANTINOPLE LETTER.

THE PLAGUE AND QUARANTINE—PARALYTIC HYDROPHOBIA—HEALTH-BOARD MATTERS.

CONSTANTINOPLE, March 12, 1901.

THE year 1901, so far, has been as remarkable for slackness in medical matters as in most other things.

Plague and quarantine for a time troubled the commercial world without exciting alarm in the population. It may almost be said that the vagueness of description of the disease and the irregularity of the quarantine caused cynical amusement.

On January 10th a case of plague was officially reported as having ended fatally in hospital at Stamboul. The patient was a certain Mehmed, a "caiqneyi," or native boatman, resident at Beicos, a village on the Asiatic side of the upper Bosporus. Quarantine of ten days against Constantinople was immediately imposed by Greece, Roumania, and Egypt; and Vaurla, which has been excluded in a former quarantine, was included in this. The old story—the doctor who attended the patient treated him for pneumonia. No other case has since occurred.

February 5th a case of plague was reported from Smyrna, and again came quarantine and disinfection, at first severe, then shortly modified; and so goes on a see-sawing form of quarantine and disinfection, which is little edifying to the hygienic cynics who think dirty streets, filth accumulations, and overcrowding as much worthy a health administration's notice and care as the "guarding the doors of Europe" against pestilence by the international delegates of the Ottoman health board.

That an alleged case of plague in such an out-of-the-way place as Beicus should have occurred is not explained, nor is it clear why, with such perfect means of isolation at hand and at the command of the sanitary council, an individual case of plague should be allowed to cause such inconvenience and loss to the shipping interests and passengers, even if the nature of the disease be confirmed by bacteriological investigation.

A case of hydrophobia is reported to have occurred in one of the suburbs. The patient died after having undergone the Pasteurian treatment. The interest of the case lies in the circumstance that the editor of the *Revue Médico-Pharmaceutique* issued a series of questions to the physicians who had seen the case, asking their opinions of the nature of the malady, which is described as "rage paralytique."

The short period of incubation and development, and especially the paralytic fever, which were considered more or less abnormal, appear to have cast doubts on the quality of the antirabic serum employed.

The patient, a man aged forty years, was bitten by a dog on January 31st. The bite was on the right leg, in the region of the tendo Achillis. The dog was examined by the chief veterinary of the school at Paucaldé and declared to be rabid. On February 4th Pasteurian inoculations were begun at the Antirabic Institution. On February 18th the patient had had fourteen inoculations, when suddenly, after coming out of a warm bath, he showed symptoms of paralysis of the lower extremities. On the night of the same day, and on the 19th, the thoracic organs and upper extremities in turn became paralyzed. Symptoms of glosso-laryngeal paralysis with complete aphonia and slight difficulty of deglutition followed. Other symptoms were negative. He had no other subjective symptoms than of stinging of hands and feet. Respiration was 24; pulse, 80; temperature, 37° C. Such, in brief, is an abstract of the case as reported by Dr. P. Remlinger, director of the Imperial Antirabic Institute. The patient died, forty-eight hours after the appearance of the first symptoms, from paralysis of the heart—twenty days after being bitten. There was no autopsy. In view of the symptoms it was asked, What is the nature of this affection—a hysterical paralysis; an acute ascending paralysis (Landry's disease); or paralytic rabies? The period of incubation was about eighteen days. The third day from being bitten he was submitted to the antirabic treatment, and it is stated that he complained of the pain of the injections. He went on foot daily to the institution and returned home after being injected. An interesting case, truly, inasmuch as the patient died from the most virulent and rarest form of rabies, in spite of the antirabic inoculations practised from almost the beginning.

Some differences of opinion have naturally had expression: *i.e.*, if this rare form of paralytic rabies might not be attributed to and classified under laboratory or experimental rabies. And the statement is made that since the foundation of the Antirabic Institution of Constantinople by Zoëros Pacha, no case is recorded among the inoculated who died presenting the form of paralytic rabies, although this form has been observed elsewhere. There are some points in common with the case of the late Lord Daneraille, who, it may be remembered, died with marked symptoms of rabies after inoculation at the Pasteur Institute at Paris. To include such cases in the paradoxical category is to exclude the possibility of a faultily prepared serum.

The international members of the Ottoman sanitary board still maintain their protest, and hold out against the palace nomination of Nanyk Bey as successor to the late sanitary inspector, Dr. Vitalis. The question has now become a diplomatic one, as the respective embassies support their delegates and have had a meeting on the subject in dispute. In the mean time a *modus agendi* has been arranged, and the affair may be indefinitely prolonged.

Dr. Clemow, the British delegate to the Ottoman health board, is down with typhoid.

Reviews and Notices.

URINARY DIAGNOSIS AND TREATMENT. By JOHN WAINRIGHT, M.D., etc. Chicago: G. P. Engelhard & Co. 1900.

THIS is a very satisfactory handbook for both the student and the practitioner, well gotten up and containing a number of good plates of the microscopic appearances in different specimens of urine. A number of diseases characterized by marked changes in the urine receive separate consideration from the therapeutic standpoint.

THE USE OF THE ROENTGEN RAY by the Medical Department, U. S. A., in the War with Spain. Prepared under the direction of Surgeon-General G. M. STERNBERG, U. S. A., by W. C. BORDEN, Captain and Assistant Surgeon, U. S. A. Washington: Government Printing Office. 1900.

THE Roentgen ray was extensively tried during the late war, and this volume embodies the results of its use by the United States army. The method seems to have been very successful, and to have been very skilfully applied. The most important part of the present work is the plates which are many and excellent. They all show how very useful the *x*-ray is in locating a missile which causes so little local disturbance as the high-velocity bullet. A number of interesting clinical histories are given with their *x*-ray findings and ultimate result, so that a really valuable contribution to the literature of the use of this aid to diagnosis is offered.

MEDICO-SURGICAL ASPECTS OF THE SPANISH-AMERICAN WAR. By Lieutenant-Colonel NICHOLAS SENN, Chief Surgeon, U. S. V., etc. Chicago: American Medical Association Press. 1900.

THIS volume embodies the experiences of its author in the war of 1898, and consists chiefly of letters upon various subjects having to do with the medical aspects of that war. Most of the subject matter is in a popular strain, and there is very little of scientific value. A few interesting cases of bullet wound are detailed, but most of the surgical cases cited are entirely without interest, and the medical cases are chiefly typhoid and malarial fevers very superficially discussed. Extended criticism is unnecessary.

Report on an Outbreak of Plague at Sydney, 1900. By The Chief Medical Officer of the Government and President of the Board of Health. Sydney: W. A. Gullick, Government Printer. 1900.

This interesting brochure contains descriptions and analyses of three hundred and three cases of plague, occurring at Sydney, N. S. W., during the outbreak of the disease in the past year. The cases are gone over carefully and are interesting from the clinical point of view, as their histories are minutely followed. Considerable bacteriological work was done at the time of this outbreak, and it receives a share of attention in the present publication.

A Text-Book on Practical Obstetrics. By Egbert H. Grandin, M.D., Gynæcologist to the Columbus Hospital, with the collaboration of George W. Jarman, M.D., Gynæcologist to the Cancer Hospital. Third edition, revised and enlarged. 8vo, pp. 511. Philadelphia: F. A. Davis Company.

The third edition of this work appears in an enlarged form, the authors having added a chapter on the anatomy and embryology of the subject. Like the preceding editions the special feature of the book is its essentially practical character not only in the text, but also in the numerous half-tone illustrations, all of which have been taken from life under the authors' personal direction. To avoid confusion the many theories and various deductions therefrom have been avoided, the object being to teach what is considered best in the most forcible manner, so that the student in doubt can have proper guidance from practical advisers. The work should be possessed by all those engaged in obstetrics, even though they have a well-stocked reference library on the subject.

A Text-Book of Pharmacology and Therapeutics; or, the Action of Drugs in Health and Disease. By Arthur R. Cushny, M.A., M.D., Aberd. Prof. of Materia Medica and Therapeutics in the University of Michigan; formerly Thompson Fellow in the University of Aberdeen and Assistant in the Pharmacological Institute of the University of Strasburg. Second edition, revised and enlarged. Illustrated with 47 engravings. Pp. 732. Philadelphia and New York: Lea Brothers & Co. 1901.

The fact that the second edition of this work has been demanded within a little more than a year from the appearance of the first issue proves that it has supplied something needed by the profession at large. What may be termed the special advantage of the author's teachings is to be ascribed to his scientific methods, for he has cut loose as much as was possible from the empiricism of the past and deals with reasons deduced from experimental research, making a system of therapeutics far more satisfactory to the practitioner. It is safe to say that works of this kind will tend to check indiscriminate medication and to upbuild drug treatment on a foundation hitherto only too weak. In this edition the changes are few, and among them we note the incorporation of the most recent articles on alcohol and salt action.

International Clinics. A Quarterly of Clinical Lectures and especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose, and Throat, and other Topics of Interest to Students and Practitioners. By leading members of the medical profession throughout the world. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U. S. A., with the collaboration of John B. Murphy, M.D., Alexander D. Blackader, M.D., of Chicago; H. C. Wood, M.D., of Philadelphia; T. M. Rotch, M.D., of Boston; E. Landolt, M.D., of Paris; Thomas G. Morton M.D., and Charles H. Reed, M.D., of Philadelphia. With regular correspondents in Montreal, London, Paris, Leipsic, and Vienna. Vol. III. Tenth series, 1900. Philadelphia: J. B. Lippincott Company. 1900.

The title tells so much and the work is so generally known that few words of commendation seem necessary. The volume now issued contains in addition to the usual collections of clinical lectures a monograph of sixty-six pages on the scientific modification of milk, by Thompson S. Westcott, of the University of Pennsylvania. There is also a symposium on genito-urinary diseases, by various well-known writers, and Dr. L. Webster Fox contributes an interesting paper on injuries of the eyelids and eyeballs.

Proceedings of the American Medico-Psychological Association at the Fifty-sixth Annual Meeting, Held in Richmond, Va. Pp. 353. Published by American Medico-Psychological Association. 1900.

In addition to the lists of officers and members and general society reports this pamphlet contains many interesting articles read by members of the society. Degeneracy, epilepsy in the insane, mental responsibility, traumatic hysteria, and many other subjects which interest the alienist are described and discussed. It makes a neat volume of interesting contents.

Chirurgie des Voies Biliaires. Par le Dr. Victor Pauchet. Avec 9 figures dans le texte. Paris: Librairie A. B. Baillière et fils. 1900.

This little brochure of less than one hundred pages takes in all modern methods connected with gall-bladder surgery from contusions to cholangiectomies.

Transactions of the Louisiana State Medical Society. Twenty-first Annual Session. 1900.

The scientific contributions presented at this session of the Louisiana State Medical Society were of a uniformly high order of merit. An interesting address on expert and opinion evidence was delivered by W. W. Howe, of the New Orleans bar.

Text-Book of Histology. By Dr. Philipp Stohr. (Third American from Eighth German Edition.) Translated by Dr. Emma L. Bilstein. Edited with additions by Dr. Alfred Schaper. Philadelphia: P. Blakiston's Son & Co. 1900.

The last edition of this excellent text-book will be again gratefully welcomed by American students of histology. New illustrations and additional text have been added by Professor Stöhr to the eighth edition, thus bringing this book to date with the latest ideas on histology and histological technique.

The A B C Manual of Materia Medica and Therapeutics. By G. Hardy Clark, M.D. Pp. 197. Philadelphia: Boericke & Tafel. 1901.

This little volume, intended for homœopathic practitioners, is a digest of the most important drugs, arranged alphabetically. Characteristics, toxic effects, dose, and therapeutic effects comprise the four headings under which each drug is treated. The doses are given in the regular and in the homœopathic methods.

Flashes of Wit and Humor; or, A Brief Study of the Best Things of the Brightest Minds. By Robert Waters, Author of "Intellectual Pursuits," etc. New York: Edgar S. Werner Publishing and Supply Company. 1900.

As the author states in his preface, the object of this little book is simply to afford an hour's recreation, a respite from care, a smile and a laugh, to those weary brain workers who are oppressed by many daily burdens. It well fulfils its aim.

Enlarged Tonsils Cured by Medicines. By J. Compton Burnett, M.D., London, England. Philadelphia: Boericke & Tafel. 1901.

It is always interesting to look at a problem from various points of view, and as the author advocates in this case ideas which are undoubtedly embraced by the minority of practitioners, his accumulated experience of twenty years is a valuable contribution to the non-operative treatment of enlarged tonsils. He states that he has been able by medicines to cure the great bulk of his cases. He uses various drugs according to the case, *e.g.*, baryta, thuja, antirheumatic remedies, etc.

King's American Dispensatory. By Harvey Wickes Felter, M.D., and John Uri Lloyd, Pharm. M., Ph.D., Professor of Chemistry, Pharmacy, and Toxicology in the Eclectic Medical Institute, Cincinnati. Entirely rewritten and enlarged. Eighteenth edition. Third revision. In two volumes. Vol. II. Cincinnati: The Ohio Valley Company. 1900.

It was over a year ago that the first part of this extensive work was reviewed in these columns. We are pleased to note the completion of the task, believing that long intervals elapsing between the parts of a work of this kind are a serious inconvenience, at least, to the possessor of the portion first appearing. The revision appears to have been very carefully made. The volume begins with "Galanga" on page 905, and ends at page 2172—followed by a general index. There are in all 260 illustrations (woodcuts). There are a number of tables of weights, doses, solutions, atomic weights, specific gravities, etc. As a whole, the work has undergone considerable improvement and new matter has been added.

Medical and Surgical Reports of the Boston City Hospital. Eleventh Series. Edited by H. L. Burrell, M.D., W. T. Councilman, M.D., and C. F. Withington, M.D. Boston: Published by the Trustees. 1900.

This is an interesting collection of clinical papers upon various subjects, by members of the staff of the Boston City Hospital. The papers cover cases observed during

the past year, and many of them are of unusual interest. Among others, those On Fracture of the Spine, On the Use of very Large Doses of Diphtheria Antitoxin, and On Tuberculous Peritonitis, cover subjects which are always important. However, all the material is useful, and it is a matter for regret that more of the hospitals in this city do not also publish similar scientific reports, instead of the usual perfunctory pamphlets on ways and means, etc.

Transactions of the Clinical Society of London. Vol. XXXIII. London: Longmans, Green & Co. 1900.

Besides the usual lists of members and reports of the society, this volume contains many instructive articles, which, in fact, form nine-tenths of the work. Unusual cases arising in the practices of the various members are described in detail and are accompanied by excellent half-tone illustrations which are most helpful. Many branches of medical investigation are thus aided by those well able to describe, comment, and observe in their special fields.

The United States Pharmacopœial Convention. Abstract of the Proceedings of the National Convention of 1900 for Revising the United States Pharmacopœia, Held at Washington, May 2, 3, and 4, 1900. Philadelphia: J. B. Lippincott Company. 1900.

This little pamphlet contains the interesting address of Dr. Horatio C. Wood, the president of the association, together with the reports of the committees and a reprint of the constitution and by-laws. It is of use to both pharmacist and physician.

Proceedings of the Pathological Society of Philadelphia. December 1, 1900. New series, Vol. IV., No. 2.

This interesting little pamphlet contains the obituary notices of Dr. Alfred Stillé and Dr. J. M. Da Costa, together with the usual scientific articles, which include Experimental Tuberculosis in Cats, the Dissemination of Tubercle Bacilli by Cows in Coughing a Possible Source of Contagion, Two Cases of Glioma of the Retina, and Description of Instruments.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Second edition, revised and largely rewritten. Vol. I. Philadelphia and New York: Lea Brothers & Co.

This illustrated work presents in its new form a reconsideration of diabetes, diphtheria, spasmodic croup, the exanthemata, typhoid, pneumonia, influenza, and a number of other diseases. Nearly half the articles are said to be entirely new, while the rest of the material has undergone a complete revision. There are also new illustrations. The chapters are briefly: General Therapeutics, H. C. Wood; Prescriptions, J. P. Remington; Sanitation, H. B. Baker; Foods, I. B. Yeo; Exercise, E. M. Hartwell; Rest Cure, J. K. Mitchell; Electro-Therapeutics, Rockwell; Hydrotherapy, Baruch; Climate, Solly; Mineral Waters, Crook; Massage, Moore; Disinfection, Coplin; Diseases of the Thyroid and Thymus, S. J. Meltzer; Rheumatism, James Stewart; Diabetes, James Tyson; Blood, Ralph Stockman; Syphilis, Edward Martin; Tuberculosis, Flick; Scrofulosis, Chrystie; Scurvy, C. E. Banks. Remington's article on prescription writing will be most useful to students. The others are written largely for the practitioner.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London, etc., and F. F. Burghard, M.D., M.S. (Lond.), F.R.C.S., etc. In seven volumes. Vol. IV. The Treatment of the Surgical Affections of the Joints (Including Excisions) and the Spine. Philadelphia and New York: Lea Brothers & Co. 1901.

Volume IV. of this excellent work covers dislocations and other injuries of joints, and the various forms of disease occurring in joints, with the treatment, so that a large part of the section is devoted to orthopædic surgery, upon which subject it is an excellent handbook. In dislocations of the shoulder the greatest prominence is given to Kocher's method of reduction, and the heel-in-axilla method is given second place in point of utility, with which conclusions practically all surgeons are agreed. The treatment of the complicated dislocations of the shoulder by operative means is well discussed. The method of treating sprains is very well given and the matter is classified in a way that should appeal strongly to the student class. Massage is given a deservedly prominent place in this connection. The authors have more confidence in the method of maintaining continuous irrigation in infected joints than we think the method which they describe justifies, though that method is the one usually recommended in surgical works. Among inflammatory conditions, tuberculosis naturally receives most attention, chiefly from the therapeutic point of view, with very little on the pathology of the subject. What the authors consider best in orthopædic apparatus receives full attention, and the subject is well illustrated. Injuries and diseases of the spine are included in this volume, and the prognosis in the presence of symptoms of spinal-cord injury is pronounced bad, so that operation does not hold out any prospect of permanent or extensive improvement. It is unfortunately necessary to recognize the correctness of this point of view. There is a chapter, contributed by a third author, upon the different forms of exercise which are useful in the correction of certain spinal deformities. The illustrations are very good and add much to the clearness of the descriptions. Volume IV. well sustains the good reputation made by the previous three sections.

Orthopædic Surgery: A Handbook. By Charles Bell Keetley, F.R.C.S., Surgeon to the West London Hospital; Member of the British Orthopædic Society; Corresponding Member of the American Orthopædic Association. London: Smith Elder & Co. American Agents, G. P. Putnam's Sons. 1900.

This is essentially a volume for the leisure hours of the practised worker, rather than a guide to put into the hands of the student, for while the author's boldness in challenging long-accepted views and theories, and his skill in upholding his own opinions, are well adapted to interest and instruct one grown old in the art, the general trend of the work is too iconoclastic to make it proper meat for less seasoned stomachs. It is a valuable contribution to the not overrich literature of this branch of surgery, since it embodies the results of many years' observation and practice in a specialty yet new enough to furnish many problems for elaboration and sufficiently complex to encourage difference of opinion, but it is to be regretted that in his zeal to overthrow the idols of Baal the author has not always paused to provide satisfactory substitutes for the theories he demolishes, and that when he does become philosophical his meaning is often obscure and hard to fathom. The chapter on scoliosis is particularly mettlesome in its attacks on current beliefs as to the causation of the deformity, but its logic, though vigorously expressed, is not always convincing, and at the end, though it is plain that, Ishmael-like, the author's hand is against every man's, his own position is not very clearly defined. The sections on treatment are perhaps the most useful and suggestive in the book and more than compensate for the defects of other portions, though it is suprising to find no mention made of tuberculous disease of the knee, while the corresponding lesion of the spine receives very careful and extended consideration. Of the numerous illustrations, those from other works and from photographs are, on the whole, very good, but the original drawings are, for the most part, poor, and some of them (witness those on pages 256 and 257) surprisingly bad.

Grundriss der inneren Medicin. Für Studierende und praktische Aerzte. Von Dr. Max Kahane in Wien. Mit 65 Abbildungen. Leipzig u. Wien: Franz Deuticke. 1901.

In this volume, dedicated to Nothnagel, the author has successfully accomplished his purpose of producing a work to occupy the middle ground between the epigrammatic terseness of the compend and the diffuse prolixity of the more pretentious system or encyclopædia. Avoiding the meticulous attention to detail that so often mars the German text-book in Anglo-Saxon eyes, he has attained the golden mean most happily, and continental Europe is to be congratulated on the appearance of a book that seems worthy of comparison with that favorite of all English-speaking students, Osler's "Practice of Medicine." The scope of the two is not quite the same, however, for, although about equal in bulk, the newer work does not contain any articles which at all approach in length or completeness the more important ones in Osler—the masterly essays on tuberculosis and typhoid fever, for example—while it is somewhat richer in its description and discussion of minor and other topics, such as acute gonorrhœa, which the American author has left to the specialist. The illustrations, which are taken from Sahli's text-book on clinical examination, are good as far as they go, but are too few in number to give the book rank as an illustrated work, and might better have been omitted altogether. Treatment is very summarily dealt with, though a number of different plans are usually indicated, which often are suggestive and vary enough from the methods in vogue in this country to be interesting. Altogether, the chief excellence of the work lies in the admirable force and clearness with which the salient points of each subject are presented, and it will be valuable to American readers desirous of viewing the medicine of to-day through foreign spectacles.

Clinical Department.

REPORT OF A CASE OF MALARIAL HÆMATURIA.

By P. L. BELLINGER, M.D.,
WATERPROOF, LA.,
EX-PRESIDENT OF THE PARISH BOARD OF HEALTH.

J. T——, white, male, aged twenty-four years, spent the major portion of his life in the Louisiana swamps. He was exposed during the last few years, through dissipation, to every possible harmful influence. On September 16, 1900, he was taken with ordinary third-day chills and fever, which lasted four days under home treatment, the patient keeping his bed till after the passage of his chill day, when he again exposed himself to the hot sun, indulging slightly in beer, returning home at a rather late hour on Friday night, September 21st. He then complained of feeling very ill and soon retired. Upon voiding his urine he noticed it had a bloody character. A physician was summoned at once, who pronounced the case one of hemorrhage from the bladder. Treatment (of the nature of which I am ignorant) was instituted, but the hemorrhages increased both in frequency and quantity. The father, who had had personal experience in swamp fever, suspected the latter in his son, and advised a change of physicians, at which time I was called—it being the fifth day of the illness—in time to witness the eighteenth hemorrhage. The diagnosis was plainly written on the man's countenance, the entire body was of a deep bronze color, intense agony was plainly denoted by his deep sighs and groans, with a restless tossing of the head; the breath was foul and quickly drawn, the tongue was heavily coated, the pulse was rapid and weak, and the temperature 100° F. Physical examination showed a normal heart and lungs; the spleen was slightly enlarged, the liver was in a high state of congestion and exquisitely tender, the abdomen was tense and slightly painful on pressure, and the bowels were inactive.

Owing to the profound infection and great loss of blood, together with his long illness and debilitated condition, I realized the importance of heroic efforts, and placed him on the following treatment, I may say, without hope: Strychninæ sulphatis, gr. $\frac{1}{40}$; liq. potassæ ♏ x. was given every four hours with gtt. v. of turpentine on sugar. ℞ Hydrarg. chlor. mitis, gr. vi.; Sodii bicarbon., gr. x.; Podoph., gr. $\frac{1}{4}$. M. ft. chart. iv.; one every hour. ℞ Pot. bitart., ʒ i.; Sod. hyposulph., ʒ ss.; Aquæ, q.s. ad ʒ vi. M. S. Tablespoonful every hour.

Milk as a diet was given in quantities of two ounces every three hours, and small quantities of beer and champagne were allowed at frequent intervals. Twenty-four hours later I again visited my patient and, contrary to all my expectations, I found such gratifying improvement that I became almost hopeful. The urine was voided three times during my absence; it showed no signs of blood, was ample in quantity, and perfect in color. The bowels had acted well—relieving the liver, thus alleviating the agonizing pain. The temperature was normal; the pulse, 85, but very weak. The skin was a little clearer. The patient was talkative and cheerful, and was slightly propped in bed and smoking a cigarette, of which I did not approve. The treatment was continued with strych. sulph. gr. $\frac{1}{60}$ every four hours. I omitted all else, and gave positive instructions about the nourishment, which was to be largely milk, alternated with concentrated beef tea. I left the man at 10:30, doing as well as I could expect. I was hurriedly called at 2 P.M. the same day, but being engaged for the moment, I reached him only two hours later, and to my great surprise he had been dead one hour, dying very suddenly, and I presume from heart failure.

Conclusions: 1. Had the above treatment been given earlier in his illness, would not the results have been better? 2. Had I, even at the late hour of my visit, supplied a circulating fluid in shape of a decinormal salt solution, would that have changed the result? 3. Alcoholic subjects in swamp fever, as in pneumonia, have small hope.

MALARIA IN A CHILD OF THREE WEEKS.

By J. C. JOSEPHSON, M.D.,
BALTIMORE, MD.

Baby Rosenfeld became ill when a week old. His mother had lived in a malarial district in the South, and had had several attacks, the last one on the eighth puerperal day. Ever since then the child had been ailing. Every afternoon, about three or four o'clock, he would become blue and have a slight spasm. Then he would have a fever. He was very restless, took the breast badly, was pale and small, and had a very marasmic look. In the morning there would be no fever. I first saw him about the twelfth day of his illness on November 30, 1900, in one of his typical attacks. The child was pale and bluish, and had a slight spasm of the muscles of the face. The breathing was jerky. The temperature was 102°. The spleen was much enlarged. He had been treated for consumption since he first became ill, by a certain ignorant but very popular practitioner, one of those "years-of-practice" men that we have here. There was absolutely nothing abnormal in the chest. The regular periodicity of the attacks, the mother's history, and the enlarged spleen convinced me that I had to do with a case of malaria, and five days' dosing with quinine—at first four grains a day and later two grains—cured the child entirely, and he has been flourishing ever since.

THE TREATMENT OF ASCITES.[1]

By ARTHUR H. BIGG, M.D.,
DETROIT, MICH.

The treatment of ascites has often proved unsatisfactory, the fluid, although evacuated, returning again and again until the case has terminated by exhaustion, or by the progress of the primary lesion. The reason for this, in the case of medical treatment, may be accounted for, in part, by the complications that usually exist, rendering necessary a careful discrimination in the use of drugs, lest, while directing our efforts energetically to the subject in hand, a line of treatment should be adopted that would be incompatible with the welfare of another organ, itself the subject of morbid action, as the heart or the stomach.

It is with the view of encouraging a brave, rational treatment of this disorder, even when seriously complicated, that I have ventured to come before you with this essay, the scope of which includes but a segment of the circle of its medical treatment, being limited to the consideration of but one principal drug and two or three of its useful congeners.

In speaking of Momordica Elaterium, I bring no new agent to your notice, but I have thought it possible that, like myself formerly, some of you may have shunned the drug, or used it with trepidation, through the fear inspired by its characterization in the books that its employment is attended with danger to the patient.

[1] Portion of paper read before the Detroit Academy of Medicine May 8, 1900.

And there is no question that the too free use of this invaluable remedy, unmodified by suitable correctives, is capable of producing unpleasant and even alarming depression, but, once having witnessed the exact and beautiful work it can be made to do, when combined with effective corrigents, there is little doubt that you would surrender your prejudice at discretion, and henceforth give it a place of distinction in the list of your therapeutic agents.

To the fathers who gave the drug its name, which means "a driver," it was a horse that frequently took the bit in its teeth and carried the poor patient perilously near the brink of the river Styx, if not into that dark stream, but then the fathers knew comparatively little of the possibilities of digitalis, still less about the sustaining power of strychnine, and nothing whatever of the efficiency of glonoin in preventing syncope and collapse. Therefore, from the point of view of a practitioner at the close of the nineteenth century, they were excusable for their failure to discover the full merit of one of the most valuable drugs in the materia medica, for could they but have put to the proof the following combination, in pill or capsule, they would, in observing its effect, have done swift justice to elaterium in their description of its capabilities:

℞ Elaterin[1] ..... gr. $\frac{1}{15}$
Strych. sulph ..... gr. $\frac{1}{30}$
Glonoin ..... gr. $\frac{1}{200}$
Ext. digitalis (Lyon's scales) ..... gr. $\frac{1}{4}$
Caffeinæ citrat ..... gr. i.
Pulv. caryophylli ..... gr. i.

M. For one capsule. S. Give one capsule every three to six hours.

I have here disclosed a formula which may be relied upon for the removal of ascitic fluid. If there be a tendency to nausea, the addition of an eighth of a grain of cocaine muriate, or the substitution of it, temporarily, for the digitalis, may be thought advisable, but, with some such necessary modifications, unless there is present an inflammatory condition of the intestinal tract, or a gastritis, I should boldly attack any case of ascites with the pill prescribed above, with the confident expectation of rapidly removing the fluid without material discomfort and with no risk whatever to the patient. I say "no risk" and use the words advisedly, within the limitation that must ever mark our discussion of the action of drugs, owing to the idiosyncrasies and complications that we meet, and which are likely to confuse our best-laid plans of attack upon intrenched disease.

It is necessary here to emphasize the importance of pushing the treatment. Four to six copious evacuations per diem may be maintained, by giving the drug as above directed, until permanent relief is obtained. Nothing need be expected from a tentative, timorous course. That way failure lies, and a broad way it is and strewn with numberless mortifying experiences and stranded reputations of apostles of the healing art who have followed its uncertain leadings. There is often found a proper field for placeboic medication, but none that can justify guess-work as to dosage, least of all the condition under discussion. It approaches as nearly exact medication as perhaps any instance in the range of therapy. What have we in such a case to contemplate? An adventitious collection of fluid in a cavity of the body that is in immediate proximity to the intestine, which, when its whole surface is considered, forms the largest secreting organ in the body, comprising, according to Meckel, no less than fourteen hundred square inches of a closely packed glandular apparatus. Such being the case, the simple problem is so to employ a natural law as to cause the filtration of the fluid through this membranous diaphragm that lies between it and the open bowel which will give it exit. The solution of the problem lies in the introduction of an irritant, which in this case is our eliminant drug, into the system, which so stimulates the nerve supply of the secretory apparatus of the bowel, that it taps the congested venous trunks of the mesenteric system, thereby causing a diversion, or exosmosis, of the watery portion of their contents into the bowel, and the ultimate reabsorption and complete removal of the pent-up accumulation of peritoneal fluid.

This I take to be the rationale of the therapeutic process that I have here sought to elucidate, and which, because of the great satisfaction it has given me in my employment of it, I wish to recommend to others for trial in cases that indicate its use.

The foregoing argument seems to justify the following conclusions:

1. By the courageous use of cardiac stimulants, combined with carminatives, the depressing tendency of the most active hydragogue cathartics, simultaneously administered, may be so obviated as to render their continuous and prolonged use entirely safe.

2. The efficacy of such cathartics, notably elaterin, when given with the object of removing ascitic fluid, is greatly promoted by the coadministration of drugs which elevate arterial tension.

3. In the treatment of abdominal dropsy with the agents suggested in 1 and 2, a coincident weak heart, so far from constituting a contraindication of such treatment, may be regarded as an incentive to a persevering trial of it, in which case good results to the heart itself may be expected.

[1] The active principle, elaterin, and not the crude drug, elaterium, should be used.

SIMULTANEOUS EXTRA- AND INTRA-UTERINE PREGNANCIES.

By F. V. CANTWELL, M.D.,
TRENTON, N. J.,
SURGEON TO ST. FRANCIS' HOSPITAL.

The following case is of sufficient rarity to justify record:

Mrs. X——, white, aged twenty-seven years, American. Father, mother, and three sisters are alive and well; one brother died in infancy. The patient had scarlet fever and whooping-cough when a child. Menstruation began at sixteen years, and was always regular, with but little pain. She married when she was twenty-three years old. She has one child, three years old. I was present at the birth of this child, and the delivery was a difficult instrumental one, under anæsthesia, followed by a pleasant recovery. One year and nine months ago she had a miscarriage at seven months; cause unknown.

I was called to see her on January 1, 1901, in consultation with Dr. Walter Madden. About four weeks before, she was taken with nausea and violent retching, with sharp pains in the lower part of the abdomen. These pains were intermittent, occurring every other day. She had missed no menstruation since the miscarriage, twenty-one months before; her last period was December 8, 1900, since which time she noticed a very slight bloody discharge. The uterus was as large as at ten weeks of pregnancy and the cervix was soft and swollen, with an open os. To the left there was a small sensitive lump. Extra-uterine pregnancy was thought of at this time, but a diagnosis of normal pregnancy was made and remedies to control vomiting were given. Her pulse at this time was 90, and her temperature over 99°.

Pain and retching persisted until she was forced to remain in bed. I saw her again on January 14th. She looked somewhat thinner, but showed no evidences

of bleeding. She had a bloody discharge, mixed with small shreds, from the uterus. My examining fingers brought away some dark, thick, bloody, shreddy mucus. The uterus had only slightly increased in size, but the growth of the tumor was marked. The cervix was deep in the hollow of the sacrum and the os was well dilated. The fundus uteri could be felt pushing out the abdominal wall, which was thin and relaxed, much to the right of the median line. Its outline could even be seen. With the middle finger in the rectum and the index finger in the vagina a soft, boggy, very sensitive, and ill-defined mass could be made out to the left. At my first visit I felt assured that the pregnancy was normal, but now I was positive that an extra-uterine pregnancy existed. A finger pushed for some distance into the uterine cavity found nothing but the velvety deciduous lining.

She complained of frequency of urination, with pain, also a feeling of fulness and pressure in the rectum. I advised removal of the extra-uterine pregnancy, and she was sent to St. Francis' Hospital for that purpose.

On arrival at the hospital she showed some evidences of bleeding, a pulse going up to 120, a temperature of $99\frac{3}{5}^{\circ}$, and considerable exhaustion.

An examination two hours before operation showed a very appreciable enlargement of the mass, due to blood clots in the pelvis.

I did not curette the uterus; first, because there was no indication of any harm from its contents and the decidua seemed to be coming away naturally. Second, because the indications of bleeding had become so pronounced that it would have been bad practice to add anything more to the exhaustion of the patient. Third, because in my experience of ten operations for extra-uterine pregnancy, without a death, the uterus always got rid of the decidua without interference. In one case a peculiar sharp rise in temperature two weeks after operation might be explained by slight infection and absorption of this membrane.

Operation, January 17th, 11:30 A.M. An incision down to the peritoneum showed the dark color of old blood in its cavity. When the abdomen was opened the pelvis was found full of fluid blood and old clots. Enough of these were removed to allow me to see that the left tube was distended, measuring about four by two inches. Its walls were so thinned out as to leave nothing but the shiny, stretched peritoneum covering them. The tube had not ruptured and the blood came from the open mouth of the fimbriated extremity through which was pushing a clot. After the ovarian and uterine arteries were secured the tube and its contents were removed. The abdomen was cleansed of all blood and clots, flushed well with decinormal salt solution, and closed with through-and-through sutures. While the belly was open I noticed that the uterus was larger than is usual in these cases, but it did not enter my mind that it contained a three-months' fœtus. The patient was in bed at 12:30 P.M. and rallied well.

At 10 A.M., on January 18th, she expelled without pain or discomfort, and without knowing it, a three-months' fœtus which looked as if it might have been alive the day before. On January 19th the membranes with the placenta and part of the cord came away entire. Distinct from the fœtal sac, yet continuous with the edge of the placenta, was a cast of the uterus. This was the deciduous membrane which had lined that part of the uterus not taken up by the placenta.

The tumor was a much dilated tube surrounding a hard, almost organized blood clot. In the centre of this clot, lined with a very delicate shiny membrane, was a cavity containing a minute fœtus, two or three weeks old. This was so softened and macerated that upon being placed in water it disintegrated. The ovary removed contained a corpus luteum.

I believe this to have been a twin pregnancy and not superfœtation. In all probability the uterine fœtus came through the tube first, and the change in the lining caused by its passage was enough to arrest the advance of the second fœtus for a time sufficient to allow of its growth to a size which hindered its journey through the tube. The right tube and ovary were left *in situ*, as they were normal. In a majority of my cases it has not been necessary to remove the opposite tube.

The tubal conception died early, probably from pressure, while the uterine fœtus throve amain until the operation caused its untimely plucking, although judging from the open condition of the uterine canal this fœtus could not have remained a much longer time.

The number of twin pregnancies reported in the literature of extra-uterine pregnancy suggests to my mind a causative relation.

Whether or not this explains the phenomena occurring in this case, it at least is a plausible theory of the cause of some extra-uterine pregnancies which has not before been exploited. I have to thank Dr. R. R. Rogers, Jr., for assistance at the operation, and Dr. M. Reddan for notes of this interesting case.

The patient left the hospital, well, on February 16th.

SUPPURATIVE PAROTITIS COMPLICATING CROUPOUS PNEUMONIA.

By ARTHUR STERN, M.D.,

ELIZABETH, N. J.

An inflammation of the parotid gland, complicating pneumonia, is an extremely rare occurrence. Juergensen, in Ziemssen's "Handbuch der speciellen Pathologie und Therapie," remarks that he himself never saw a case. He mentions that in the hospitals of Vienna this complication was met six times in five thousand and seven hundred and thirty-eight cases, that is, one in a thousand, and that Grisolle mentions it as a very rare combination. This author says that parotitis is mostly found in persons older than sixty years, and in the gland of one side only, but that one completely diseased. He further mentions that the development of the inflammation takes place rapidly; the result is putrefaction or gangrene. He says the complication is extremely dangerous. It was my good fortune to see the following case:

Mrs. B——, German, about sixty-five years of age, a thin woman, previously in good health, was taken sick suddenly February 18, 1900, with a chill. I saw her the following day, when she presented all the typical signs of a croupous pneumonia of the left side. The case in itself did not show anything extraordinary, except the low temperature very often found in pneumonia of old people. The crisis took place in the night of February 26th–27th. On the 28th, she complained of pain in the left cheek, which, on examination, presented the picture of an acute parotitis.

Fluctuation being present on the 4th of March, I made an incision under Schleich's local anæsthesia and a considerable amount of pus was discharged. A specimen of this pus was examined bacteriologically, and a diplococcus was found, which was thought to be identical with the diplococcus pneumoniæ. Healing was very slow, as the whole gland sloughed away. The patient was well by the 15th of April.

The interesting feature of this case is the presence of a diplococcus. It could be easily explained by a migration of the germ into the gland through the mouth by the ductus stenonianus. But, as a rule, suppurative parotitis is considered a metastatic trouble, as we sometimes meet it in general septicæmia or puerperal fever. Taking this as the case, the germs

could be transmitted into the gland only through the blood.

But should pneumococci be present in the blood, the prognosis would be very unfavorable for the patient, as it has been demonstrated by Kohn that the presence of pneumococci in the blood is very dangerous. Among thirty-nine cases of pneumonia he found pneumococci nine times; seven of these patients died, two were cured, but these two had a severe pyæmia with abscesses and empyema respectively.

A NEW LOCAL TREATMENT FOR ERYSIPELAS.

By G. LENOX CURTIS, M.D.,
NEW YORK.

In 1889 I worked out a method of treating erysipelas, by which method the positive germicidal action of sulphate of sodium in connection with oxygen was conclusively established. I found the sulphate had so great an affinity for oxygen that when applied to a part affected by erysipelas the germs that produced the disease were deprived of sufficient oxygen to maintain life, and in a few hours were dead and resolution had commenced.

My experiments in this line were wholly clinical, and I derived so much satisfaction from them that I have depended altogether upon this method, in the external treatment of this disease. The treatment consists in thoroughly cleansing the parts affected, particular attention being given to the absolute removal of all greasy substances. A sufficient quantity of sodium sulphate is mixed with cold distilled water to make it of the consistency of a thick poultice, the diseased part is covered with a single layer of gauze or coarse cheesecloth, and over this is spread a thick layer of the sodium sulphate, care being taken that it extends considerably beyond the margin of the disease. To keep the poultice in place the whole of it is covered with a layer of the material used to cover the diseased surface (gauze or cheesecloth) and this is secured in such a way that it cannot be displaced. Ice water must now be applied to the poultice, for the double purpose of producing coldness and moisture, the object being to reduce the inflammatory action, already established, and to prevent incubation. When the disease is on the face I insert tubes in the nose or mouth to allow free breathing, and am very careful to pack around the tubes. I have found that from six to eight hours of this treatment is sufficient to destroy all the germs present. Should, however, there be any manifestation of their return, or indications that they have not been thoroughly eradicated, I repeat the treatment. It has occurred to me that possibly this treatment might be effective in other skin diseases. If so it has a great advantage over ichthyol and the iron preparations, as it does not produce the disagreeable discoloration that follows their use. I have repeatedly demonstrated this method to physicians, and whenever I have done so it has always received their approval and commendation. My attention has been recently called to the fact that when some other methods have been used to effect a cure, it has taken weeks and even months to accomplish that result. And that is the reason I wish the profession to have a knowledge of this method that has been so efficacious and satisfactory to me.

March 21, 1901.

Therapeutic Hints.

Quinine by hypodermic injection is best given in the form of the bihydrochlorate or basic hydrochlorate:

℞ Basic hydrochlorate of quinine..... 3 gm.
Antipyrin..... 2 "
Distilled water..... 6 "
M. S. Inject 1 to 2 c.c. daily.

—Kelch.

In Dysmenorrhœa with nerve storms and without local disease, give the Weir-Mitchell treatment in private practice; in hospital or among the poor give after each meal:

℞ Phosphor..... gr. $\frac{1}{60}$
Ferri valerianat.,
Zinci valerianat.,
Quin. sulph.,
Extract. aloes.....āā gr. i.

The following mixture should be taken as soon as the pains commence, and may be repeated in three hours if they are not altogether relieved:

℞ Tinct. cannabis indic..... ♏ x.
Syr. chloral hydrat..... ♏ xx.
Glycerin..... ʒ i.
Aq. camphor.....ad ʒ i.
For one dose.

It is well to give only two doses in any given twenty-four hours, because many women show symptoms of considerable excitement, with giddiness and even delirium, after repeated doses of Indian hemp. The use of cod-liver oil is still more important.—Bedford Fenwick.

A Pleasant Insufflation to keep the nose healthy:

℞ Menthol..... gr. iij.
Ac. boric..... ʒ i.
Bism. subnit..... ʒ iss.
Pulv. benzoin..... ʒ ss.
M. S. Reduce to a fine powder, and inhale forcibly.

—Ben H. Brodnax.

Anodyne and Antispasmodic.—

℞ Hyoscyamine,
Glonoin.....āā gr. $\frac{1}{60}$
Cocaine..... gr. $\frac{1}{8}$
S. At dose, watching for physiological effects.

—M. G. Price.

Vomiting of Pregnancy.—

R Menthol..... 2
Ol. oliv. opt..... 10
M. S. Ten drops on sugar when nausea occurs.

—Weil.

Carious Teeth.—Place in the painful cavity a plug of cotton soaked in

℞ Codeine..... gr. $\frac{1}{4}$
Oil of cloves..... ʒ ss.
Chloroform..... ʒ iss.

—Freemyer.

To Abort Pneumonia in Children.—The following was successful in a child of eleven years:

℞ Tinct. verat. virid. (Norwood)..... gtt. vi.
Tinct. aconiti rad..... gtt. ij.
Aq. destill.,
Syr. tolutan.....āā ʒ ss.
M. S. Teaspoonful every half hour for five doses, then a teaspoonful every hour.

—Illoway.

Urticaria.—

℞ Potass. carbon..... gr. x.
Aquæ..... ʒ iv.
M. S. Teaspoonful every hour.

—H. T. Webster.

Lumbago is benefited by applications of equal parts of tincture of iodine and liquid ammonia in collodion.

Hay Fever.—To prevent its onset, wash the inner nares with one part of hydrogen peroxide and two parts of boiled water for three days before the usual date of onset, using a pint of the solution. In sensitive conditions use in an atomizer eight grains of boric acid to two ounces of a five-per-cent. solution of cocaine and give

℞ Iodide of ammonium..... ʒ i.
Fl. ext. grindelia robusta..... ʒ iv.
Fl. ext. yerba santa..... ʒ iv.
Water.....to make ʒ ij.
M. S. Teaspoonful four or five times daily.

—Alex. Rixa.

Paralysis Agitans.—There is no specific treatment, and palliative measures are alone advocated. Hydrocyamine acts upon the motor phenomena. The hydrochlorate or the amorphous salt (Grasset) may be used in granules of 1 mgm. each, gradually increasing the dose up to 4 or 5 mgm. and again gradually decreasing. Perhaps duboisine is more in favor than the former:

℞ Duboisin. sulphat..... 0.01
Aq. laurocerasi..... 20
M. S. A syringeful containing one-quarter of a milligram by subcutaneous injection.

—Dujardin-Beaumetz.

Or—

℞ Solaninæ..... 0.01
Pulv. hyoscyami..... 0.02
Sodii bicarb..... 0.20
M. S. To be taken in the twenty-four hours.

—Sainton.

Or—

℞ Sparteinæ sulphat..... 0.10
Syr. aurantii flor..... 20
Aquæ destil..... 100
To be taken in twenty-four hours.

—Potts.

Borate of sodium is highly spoken of by some, in doses up to five or six grains daily. Collins makes a good suggestion to alternate duboisine or hyoscine with gelsemium or veratrum viride, gtt. x. of the tincture three times daily.

Acute Nasal Catarrh.—

℞ Morph. hydrochl. seu sulphat..... gr. v.
Pulv. acaciæ..... ʒ ij.
Bism. subnit..... ʒ vi.
M. S. A pinch four or five times daily.

—Ferrier.

Dysmenorrhœa.—

℞ Succi conii..... ʒ vi.
Potass. brom..... ʒ iij.
Spir. chlorof..... ʒ ij.
Aq. camphoræ.....q.s. ad ʒ viij.
M. S. Two tablespoonfuls at dose.

Acute Rheumatism.—

℞ Sodii salicylat..... ʒ ss.
Potass. iodidi,
Methyl salicylat.....āā ʒ i.
Ext. cimicifugæ fld..... ʒ ij.
Spir. vini rect..... ʒ ss.
Aquæ.....q.s. ad ʒ iij.
M. S. Teaspoonful t.i.d.

—*Pittsburgh Free Dispensary.*

Locally:

℞ Ol. gaultheriæ,
Spir. chloroformi.....āā ʒ ss.
Lin. saponis..... ʒ iij.
M. S. Rub in freely and apply cotton batting.

—Hatfield.

Supra-orbital Neuralgia.—Give fifteen grains of salicylate of sodium, and repeat if necessary.

Fissure of the Anus.—Conitzer obtained most satisfactory results in the treatment of anal fissures with ichthyol. The fissure is first anæsthetized with cocaine, and pure ichthyol is applied with a bit of cotton on a glass rod. For subsequent applications, which are made every other day, anæsthesia is generally unnecessary. Cicatrization is usually very rapid, and stretching of the sphincter is not necessary. The bowels must be kept free.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 13, 1901:

	Cases.	Deaths.
Tuberculosis	253	173
Typhoid fever	29	14
Scarlet fever	619	50
Measles	348	10
Diphtheria and croup	285	47
Smallpox	44	11
Varicella	72	0
Cerebro-spinal meningitis	0	7

Purpura as a Symptom.—The following conclusions are drawn by Oddo and Olmer as the result of their extensive researches: 1. Purpura may appear without apparent alteration in viscera, but may be relative to certain visceral lesions. 2. Such relations may be very variable, the visceral lesion being prior, contemporaneous, or subsequent. 3. When prior, the visceral lesion may have been the point of entrance for bacterial infection. 4. In many cases the visceral lesion acts by merely altering the nutrition through auto-intoxication or otherwise. 5. In a large number of cases the previous visceral lesion has a less direct action on the other tissues. There is perhaps rather an induced predisposition caused by the lesion. 6. In other cases there is a concomitant visceral lesion and purpura, both occurring equally. In this class are many cases of renal disease, but also gastro-intestinal, hepatic, pulmonary, and cardiac cases. 7. Visceral hemorrhage appears as an unusual feature in some particular cases Lastly, it is possible that a remote series of changes may be set up as the result of purpura in some organs.—*The Birmingham Medical Review*, July, 1900.

The Vital Statistics of France.—A recent short communication by M. Henri Monod to the French Académie de Médecine gives some interesting details of French vital statistics. Incidentally it shows how far behind Germany and this country France stands in this respect. The statistics relate to towns only with a population exceeding 50,000 and go back only to the year 1886. Such towns number 584, having a population which is just about one-third of the total population of France, which is 38,000,000. The statistics for the thirteen years 1886–98 show a steady diminution in the birth rate compensated for by a slightly larger diminution in the death rate. As is well known, the distinguishing characteristic of the vital statistics of France is the feeble excess of the birth rate over the death rate. Thus the birth rate, which had been 24.05 per 1,000 in the period 1887–90, fell in the period 1896–98 to 22.90, while the death rate in the same period fell from 24.56 to 21.36 per 1,000. As in other countries, urbanization of the population is rapidly progressing. Thus, while in the decennium 1886–96 the total population of France increased 0.89 per cent., the population of towns with more than 5,000 inhabitants increased 11.52 per cent., implying a considerable decrease among other parts of the community. Furthermore, the increase of population was greatest in the largest towns, varying from 1.3

per cent. in towns of from 5,000 to 10,000 inhabitants, up to 18 or 20 per cent. in towns of more than 30,000 inhabitants. Infantile mortality is extremely high in France. In the years 1896–98 it reached the number of 247 annual deaths under one year of age per 1,000 infants and had been in 1887–90 at the still higher rate of 317 per 1,000 infants. Of the total deaths at this age, 39.9 per cent. were due to infantile diarrhœa. These figures sufficiently indicate that the vital statistics and public health are both at a low ebb in France, and that much persistent and steady work is required in order that that country may overtake its neighbors in an important branch of civilization.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 12, 1901:

		Cases.	Deaths.
Smallpox—United States and Insular.			
California, Los Angeles	March 23d to 30th	1	
Oakland	March 16th to 23d	1	
San Francisco	March 23d to 30th	7	
District of Columbia, Washington	March 30th to April 6th	2	
Florida, Jacksonville	March 30th to April 6th	19	
Illinois, Chicago	March 30th to April 6th	9	
Indiana, Evansville	March 23d to 30th	1	
Terre Haute	March 18th to 25th	1	
Iowa, Clinton	March 30th to April 6th	1	
Ottumwa	March 16th to 23d	1	
Kansas, Wichita	March 30th to April 6th	17	
Kentucky, Lexington	March 30th to April 6th	8	
Louisiana, New Orleans	March 30th to April 6th	8	2
Shreveport	March 23d to April 6th	4	
Michigan, Detroit	March 30th to April 6th	3	
West Bay City	March 30th to April 6th	2	
Minnesota, Minneapolis	March 30th to April 6th	20	
Nebraska, Nebraska City	March 2d to 23d	7	
South Omaha	April 1st to 6th	6	
N. Hampshire, Manchester	March 30th to April 6th	6	
New Jersey, Newark	March 30th to April 6th	2	
New York, New York	March 30th to April 6th	42	8
Ohio, Cincinnati	March 29th to April 6th	2	
Cleveland	March 30th to April 6th	35	2
Pennsylvania, McKeesport	March 30th to April 6th	1	
Philadelphia	March 30th to April 6th		1
Pittsburg	March 30th to April 6th	3	
Steelton	March 30th to April 6th	1	
Rhode Island, Riverpoint	March 10th to April 8th	5	
South Carolina, Charleston	April 2d	*	
Tennessee, Memphis	March 30th to April 6th	22	1
Nashville	March 30th to April 6th	14	
Utah, Salt Lake City	March 30th to April 6th	28	
Virginia, Roanoke	March 1st to 31st	71	4
West Virginia, Wheeling	April 1st to 8th	2	
Wisconsin, Green Bay	March 31st to April 7th	2	

* A few.

Smallpox—Foreign and Insular.

The Use of Calf Lymph in Epidemic Smallpox.—One of the great advantages possessed by the glycerinated calf lymph now used for vaccination, over the older method of direct vaccination from arm to arm, the facility, namely, with which large quantities of it can be quickly prepared when required for purposes of revaccination in case of threatened epidemics, is well illustrated by the events which have lately taken place in Glasgow, where smallpox has assumed epidemic proportions. Many hundreds of cases have occurred, and as a not unnatural result a great demand for revaccination has arisen—a demand so great as to have already led to the performance of the operation in nearly a quarter of a million cases since the outbreak began. It would clearly have been quite impossible to effect anything approaching such an extensive revaccination by the older methods, from arm to arm, and even with tubes it would have been very difficult to obtain a sufficiently large supply of human lymph of a good quality. With calf lymph, however, all is plain sailing.

Gift of Dr. Storer to Boston.—Dr. Chadwick, the librarian of the Boston medical library, the new building of which was opened in January, referred in the following terms to a presentation to the library by Dr. Storer: "Within the past month we have received from Dr. Horatio R. Storer, of Newport, R. I., formerly of Boston, the gift of a most remarkable collection of medical medals, numbering twenty-three hundred pieces. Only two other collections exist in the world commensurate with this, that of Dr. Joseph Brettaur, of Trieste, and that belonging to the library of the surgeon-general's office in Washington. Of the six other great collections that have been formed during the past two centuries, all have been scattered except that of Rueppelli, which was bequeathed to the Seargenbergische Gesellschaft of Frankfort. Considered either from its historic interest, its æsthetic merits, or its pecuniary value, I consider this gift the most noteworthy that this association has so far received. It is to be known as the Storer collection of medical medals, in memory of Dr. D. Humphreys Storer, the father of the donor, and it is to be in charge of a son of the donor, Dr. Malcolm Storer, an accomplished numismatist."

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

EXPERIENCES WITH TRACHEOTOMY.[1]

By JOHN ROGERS, Jr., M.D.,
NEW YORK,
VISITING SURGEON, GOUVERNEUR HOSPITAL.

The performance of a tracheotomy is generally postponed to the last possible moment, owing to the dread of various possible dangers and difficulties which experience shows are greatly overestimated. Asphyxia at the time of the operation from inhalation of blood, or subsequent sepsis and pneumonia, or tracheal granulations or cicatrices, are not to be feared so much as a prolonged and exhausting dyspnœa. This was forcibly impressed upon me by my first case of chronic laryngeal stenosis. A middle-aged man in fair general condition entered the hospital with rather marked laryngeal obstruction. This had existed for several days, and seemed to place him in no immediate danger, although he had to remain in a semi-recumbent position. But while I was considering the advisability of palliative treatment, he suddenly dropped dead. It was apparently from exhaustion and syncope.

In suitable cases, and they can hardly be mistaken, tracheotomy is such a humane and life-saving procedure that there should be no hesitation in adopting it, even if the only instrument at hand is a penknife. The operation itself is so simple that the narration of the following cases must largely consist of the preceding and subsequent history.

Case I.—C. M. D——, twenty-five years of age, was admitted to Gouverneur Hospital August 18, 1896, suffering from severe laryngeal dyspnœa. She could breathe only while in a sitting position and by using all the accessory muscles of respiration. Laryngoscopic examination showed simply a general thickening of the whole interior of the larynx. There was an indistinct specific history, beginning in 1893, followed by hoarseness and aphonia. The present difficulty in breathing began in April, and had gradually grown worse. Immediate tracheotomy was attempted under general ether anæsthesia. As the recumbent position almost stopped respiration, the anæsthetic had to be given with the patient propped up by sandbags. This made the neck difficult of access, and with the first few whiffs of ether the larynx closed completely and struggling began. While she was forcibly restrained, the knife was plunged into the median line, just below the lower edge of the thyroid cartilage, which was grasped by the fingers of the left hand. The wound was dilated by the finger, a cannula inserted, and the patient restored to consciousness by artificial respiration. Inspection then showed that the cricoid cartilage and first two rings of the trachea had been divided. In the haste of the operation a considerable amount of blood entered the trachea, but recovery was uneventful. There were no appreciable rise of temperature and no bronchitis or pneumonia, and on the fourth day the patient was out of bed.

[1] Read before the section on surgery of the Academy of Medicine, February 11, 1901.

The subsequent history illustrates the difficulties in treating chronic laryngeal stenosis, and also shows how roughly such a larynx can be handled. The condition did not improve, and, in addition, a firm cicatrix developed just above the tracheal fistula. On November 15th, under chloroform, with the assistance of Dr. O'Dwyer, this was forcibly dilated with urethral sounds passed from below up and a large metal intubation tube inserted. It had to be vigorously pushed from above, while counter-pressure was made on the outside of the larynx. This was worn with comfort for a week, and then suddenly became clogged with mucus, and was extracted just in time to prevent death from asphyxia. I have never since then dared to use a metal intubation tube.

In January another attempt at prolonged intubation was made with a hard-rubber instrument, but difficulty in swallowing, a complication much more common in adults than in children, forced abandonment of the treatment.

Two years later, or in February, 1899, the larynx was opened in the median line, from the tracheal fistula to the hyoid bone. It was found almost completely obliterated by dense cicatricial tissue, and its lumen could only be followed as one follows the urethra in cases of impermeable stricture. Some attempt was made to excise the cicatrices, but the resulting space was only an open wound with more or less collapsible walls. An intubation tube was then inserted and kept from being coughed out by an attachment which could be screwed into the tube at a right angle through the fistula. This was carried in the larynx with comfort for three months, and then removed, as a cure seemed assured. But twelve hours later there was a fit of coughing, followed by dyspnœa, and the cannula had to be replaced. Further treatment was refused until April, 1900, when, under chloroform, the larynx was again dilated with urethral sounds and the intubation tube reinserted. This time it was retained four months, but after removal there was a repetition of the previous experience.

I have not the least doubt that this woman could be cured by intubation continued uninterruptedly for about eight months or a year, and I intended to follow this course, but the patient was nervous and excitable, and addicted to beer, and the gastritis from which she constantly suffered seemed to be aggravated while she was wearing the tube, and caused some eructation of gas, which she firmly believed would choke her. These eructations were her sole complaint, and led her to insist upon removal of the tube too soon. Some œdema of the incompletely atrophied tissue seemed to follow, and she would then become frightened and refuse treatment.

The noteworthy matters bearing upon the subject of the paper in this case are the following:

The attempt to administer ether for the original tracheotomy caused the already obstructed larynx to close tightly. The operation had, therefore, to be performed in haste and under difficulties, and the opening was made too high or through the cricoid cartilage.

Two years later the laryngotomy showed that above the fistula the larynx was completely filled with cica-

tricial tissue. Its tortuous lumen was represented by a mere thread of mucous membrane. The condition was a great deal worse than at the time of the first operation, and was undoubtedly largely the result of it, as it is well known that the nearer to the vocal cords a so-called tracheotomy is placed the worse is the subsequent cicatrix above it.

It is also worth remarking that, in spite of the roughest kind of handling in this case in rapid dilatation and intubation, there was never even a bronchitis.

Case II.—M. C——, forty-two years of age, was admitted to Gouverneur Hospital on December 16, 1898, suffering from severe laryngeal dyspnœa. There was an indistinct history of syphilis, with hoarseness and aphonia, culminating in dyspnœa, which had gradually increased during the last two months. Laryngoscopic examination revealed only a general thickening of all the intralaryngeal soft parts. I very foolishly attempted an immediate tracheotomy under general ether anæsthesia. As in the previous case, a recumbent position was impossible, and the ether vapor or the excitement and struggling, or both, caused the larynx to close. Forcible restraint was necessary, and as breathing had ceased anyway, the head and neck were extended, the thyroid cartilage was grasped and steadied with the left hand, and an attempt made to expose the cricoid and trachea. But death from asphyxia seemed so imminent that the hemorrhage and landmarks were disregarded, and the knife was simply plunged in as near as possible to what seemed the median line and sawed down. I then could not make the dilator enter the trachea, and so forced my finger through the wound, and followed it with the cannula. With the aid of artificial respiration the patient was finally restored to consciousness. The cannula, however, could be kept in place only with difficulty, and it was discovered that the cricoid and the first two rings of the trachea had been cut well over on their right aspect. But I did not enlarge the wound transversely, as I feared subsequent cicatrices. The temperature began to rise on the following day, and there was some emphysema of the neck. Considerable cellulitis followed, and was accompanied by a suspiciously erysipelatous blush, but, under wet dressings, the infection subsided. The malposition of the tracheal fistula, however, gave constant trouble, as the cannula frequently slipped out of place, causing immediate recurrence of the dyspnœa and a resort to the dilator to reinsert the cannula through the crooked wound. It is interesting to note that beyond the emphysema and cellulitis no other complications arose.

Ten days after the tracheotomy, or on December 27th, as the laryngeal stenosis seemed to be growing worse, Dr. W. K. Simpson, under cocaine anæsthesia, introduced an adult, hard-rubber intubation tube. He used all the force the inserter could bear while I made counter-pressure on the outside of the larynx and guided the tip of the instrument past the fistula. Feeding proved very difficult, as is usually the case in adults, but the patient finally learned to take liquids through a tube in the Casselberry position. At the end of a week the tube was coughed out and not afterward replaced, as there was no return of the dyspnœa. The fistula rapidly contracted to a small sinus, from which, in the latter part of January, there was discharged a piece of necrosed cartilage about three-eighths of an inch square. This was apparently a portion of the lateral half of the cricoid through which the original incision had penetrated.

In this case, as in the previous one, ether anæsthesia was unwise, as the vapor seemed immediately to increase the dyspnœa to complete obstruction. The danger of speedy death from asphyxia and the struggling combined to make a careful tracheotomy impossible, and the opening was, therefore, made too high and at one side. This lateral position favored the escape of mucus into the deeper parts of the neck, and the frequent manipulations for the insertion of the displaced cannula led to serious infection. Recovery, to be sure, occurred, but it might properly be ascribed to "good luck" more than anything else. The cicatricial stenosis, so common after crico-tracheotomy, probably did not develop because the wound was allowed to heal promptly. The loss of a portion of the cricoid cartilage has produced no ill effects.

Case III.—D. C——, five years of age, was seen in consultation October 11, 1900, and was suffering from severe laryngeal dyspnœa. There was a history of hoarseness and cough, beginning in 1897. In 1898 some "pieces of flesh" had been removed from the larynx with instruments by a specialist. Some temporary improvement followed, but a few months later the child became aphonic, and began to have dyspnœa on exertion. On October 5, 1900, she had caught cold, and the dyspnœa became more marked. I was called to intubate on October 11th, and found cyanosis, with stridulous and very difficult breathing. The temperature was 100° F.; pulse, 140. There was some bronchitis, but no pharyngitis nor tonsillitis could be discovered.

The history seemed clearly to indicate papilloma, complicated by acute laryngitis, and I decided upon a preliminary tracheotomy, as I had recently heard a colleague narrate a fatal experience with an exactly similar case, in which, at the autopsy, masses of papilloma had been found to have been forced down in front of the intubation tube and firmly wedged, like a gun-wad, in the lower part of the trachea, thus causing immediate asphyxia.

Under chloroform anæsthesia the trachea was carefully opened in the median line, just below the cricoid cartilage. It was noticeable that there was very little struggling, and the chloroform did not increase the dyspnœa. The wound was held apart by forceps, and the trachea and larynx were found almost completely filled with masses of friable and seemingly pedunculated tissue. It bled freely at the slightest touch, and this aided in concealing its true character. This was then scraped out with a sharp spoon, and as large an intubation tube as would pass with slight force was inserted through the larynx with the idea of stopping the rather troublesome hemorrhage, and at the same time of producing a pressure necrosis or atrophy of any of the supposed papillomata which might have escaped the curette. The wound was drawn together loosely with catgut. The child recovered quickly from the anæsthetic, and in a few hours took water and afterward milk through a tube in the Casselberry position. Late that evening she insisted on sitting up in bed, and while reaching for a glass of milk, without any previous warning, suddenly dropped dead.

I did not suspect the true cause of the trouble until I received the pathologist's report that "the excised tissue consisted of masses of fibrin and pus and represented an acute process of diphtheritic type." It was an instance of laryngeal diphtheria and heart failure. No autopsy was obtainable, but with the long history of aphonia and dyspnœa I do not doubt that there were also papillomata.

Chloroform did not aggravate the dyspnœa, as has been my experience with ether, and should be used when a general anæsthetic is necessary. The hemorrhage produced by scraping the interior of the trachea looked alarming, but was mostly coughed out, and ceased entirely after intubation—at least, there was no evidence afterward to the contrary in the wound or the expectoration or behavior of the patient.

Case IV.—J. M——, thirty-six years of age, was admitted to St. Francis Hospital May 15, 1900, on the

verge of asphyxia from what appeared to be laryngeal stenosis. He was propped up in a chair, deeply cyanosed, covered with sweat, and with cold extremities. Breathing was stridulous, or rather of a noisy, choking character, in slow gasps, and required the vigorous exercise of all the accessory muscles of respiration. He was only semi-conscious and could not articulate, and no history was obtainable. A few minims of cocaine were hastily injected in the middle line of the neck, and the upper extremity of the trachea was exposed and opened with the patient held in a sitting posture, as recumbency completely closed the air passages. There was no struggling nor increase of dyspnœa, and consequently the operation could be done with care and properly.

To my dismay no relief followed the insertion of a cannula, and he seemed about to die, when I seized a stomach tube, which happened to be on an adjoining table, and pushed it, open end down, about five inches into the trachea. There was an immediate long, comfortable inspiration, and breathing became regular and easy, and continued so with this aid alone for over a week, or until a long, flexible wire cannula could be made.

After the operation, it was ascertained that difficulty in breathing had begun suddenly three weeks previously after heavy lifting. It subsided in about half an hour, but was severe while it lasted. Another attack occurred a week after the first, and again followed exertion. Between the attacks there had been no change in the voice and no dyspnœa. The second attack was subsiding, but on the morning of the day he was admitted to the hospital it had suddenly become severe and urgently required relief.

While he was wearing the cannula, it was noticed that the instrument might become plugged with dried mucus, and yet breathing could be carried on through the space around the tube without much difficulty. The long cannula could also be removed after some days, and respiration would continue natural for a longer or shorter time and then suddenly be almost completely obstructed. The left vocal cord was found paralyzed, and this led to a diagnosis of probable aneurism of the aorta, though no other physical signs of this condition could be discovered. The intermittent character of the dyspnœa was very puzzling. After the tracheotomy and all the subsequent manipulations with the cannula, there was never any rise of temperature, nor any disturbance whatever.

On June 1st the dyspnœa recurred in spite of the long cannula, and I expected death from asphyxia. A certain low point of obstruction could not be passed with any instrument. The man was fully conscious of all efforts made in his behalf, and was every minute becoming worse. As a last resort I inserted my finger through the fistula, and thrust it down until I could feel the aneurism pulsating on the tracheal bifurcation. I continued to press as the patient struggled over on his left side, when my finger slipped by the tumor, lifting it up and entering the left bronchus. I thought I had burst the aneurism into the mediastinum, but was relieved to find that the dyspnœa had been relieved. Consciousness soon returned, and perfect comfort followed for ten days. Then suddenly the aneurism ruptured into the trachea, and death followed within a few seconds.

Though these last two cases terminated fatally, the result cannot be ascribed to the tracheotomy or subsequent manipulations. Chloroform in one instance and cocaine in the other lessened the difficulty of the operation as compared with those cases in which ether was used. The necessity of operating with the patient in the sitting or semi-recumbent posture is noticeable.

The following cases were reported by me in the *Annals of Surgery* for May, 1900, as instances of laryngeal stenosis, and so will be only briefly referred to here in their bearing upon tracheotomy. They all followed diphtheria and intubation:

Case V.—M. M——, eight years old, had diphtheria and was intubated in the Willard Parker Hospital in May, 1896. The stenosis persisted, and the larynx was curetted in July, and a laryngotomy performed in October, and again a year later (October, 1897). Slight improvement followed intermittent dilatation, but the tracheal cannula had to be retained. She was admitted to Gouverneur Hospital in January, 1900, with a deformed but pervious larynx. There was no record of pneumonia, bronchitis, or infection during all this time.

I followed my usual course in these cases, and intubated with as large a tube as the larynx would admit and closed the tracheal fistula. The intubation was difficult, as the larynx, probably as the result of the numerous operations, was misplaced forward under the hyoid bone, and was not easy to enter. The same difficulty was encountered when the tube was changed in March, but the fistula had not entirely healed, and so respiration, impossible through the larynx, was not completely cut off. But at the next change in May the wound in the neck had closed, and when the tube was removed respiration ceased. I could not make the instrument enter the larynx, and after two or three ineffectual trials, as death seemed imminent, I plunged a knife into the centre of the old cicatrix until firm resistance was encountered. The incision was lengthened downward, dilated with the little finger, and a cannula inserted. Artificial respiration finally revived the patient, though at first I feared the œsophagus had been entered, as breathing had stopped, and there were no escape of air from the wound and no coughing. The wound was then found to have been made through the remains of the cricoid cartilage and the first one or two rings of the trachea—a laryngo-tracheotomy or high tracheotomy. Intubation was then accomplished, the cannula removed, and recovery was without incident.

At the next change of the tube, for cleansing, in July, I first reopened the trachea at the site of the old wound to prevent any repetition of the last experience. There then seemed some improvement in the larynx, and I inserted a specially made tube with a circumference greater than the largest stock size. At the next change, in October, natural respiration, though difficult, was for the first time possible. But intubation was still necessary, and as auto-extubation had never happened, the child was sent home. This accident, however, occurred two weeks later, but, though there was some dyspnœa, she managed to breathe for more than six hours, when she was again intubated. The tube was changed in the latter part of November, but, though the larynx remained open, there was enough dyspnœa to make it seem wise to continue the treatment.

Case VI.—C. S——, five years old, was intubated for diphtheria at the Willard Parker Hospital in May, 1898, and was brought to Gouverneur Hospital in June, 1899, still breathing through an intubation tube. She was treated like the last case, with large tubes changed as seldom as possible until March, 1900, when a cure seemed obtained. But a week later the dyspnœa suddenly returned at night, and the house surgeon performed an impromptu high tracheotomy, I believe with a penknife—at any rate, there was no time for preliminaries, as the child had become unconscious when he arrived. The knife was simply plunged into the trachea high up, the wound dilated with forceps, and a cannula inserted. As usual in these emergency cases, the cricoid cartilage was cut. The following day the cannula was removed, and the obstruction, whatever it was, was found to have subsided. There

was no difficulty in breathing when the fistula was occluded. Some infection of the wound, however, followed, and a week later the supraclavian fossæ became swollen, and eventually a considerable abscess was opened on each side of the base of the neck. During the first week in May the dyspnœa began to recur and demand relief.

Under chloroform, which did not perceptibly increase the difficulty in breathing, it was found impossible to pass any instrument through the larynx from above. The obstruction was located at the upper end of the high tracheotomy cicatrix. There was no difficulty above this. The trachea was, therefore, again opened just below the cricoid cartilage, and the incision revealed a dense cicatricial stricture, no evidence of which had existed before the first tracheotomy, and it is, therefore, fair to presume that it resulted from that operation. The stricture was dilated rapidly with urethral sounds until a specially made large intubation tube could be inserted. There was no reaction from this somewhat rough handling. The tube was changed in August, and again on October 1st, and then a cure seemed assured. But the dyspnœa began gradually to reappear, and on October 13th the tube was reinserted, and left until November 20th. Since then there has been no difficulty, except that articulation is possible only in a hoarse whisper. I expect that this will improve in the course of time, as it has done in my other cases, until a fairly good voice is obtained.

Case VII.—I. B——, eight years old, was intubated in the Willard Parker Hospital in December, 1896; she was tracheotomized there for uncontrollable auto-extubation in March, 1897, and again intubated and finally transferred to Gouverneur Hospital in October, 1897. A week after admission auto-extubation occurred, and her trachea was opened rather high in the site of the old cicatrix by the house surgeon in a very impromptu manner. An old knife and a pair of scissors, which happened to be in the ward, were the instruments. But the child's life was saved, and no disturbance of any kind followed. In January, 1898, I performed a laryngotomy, and made the condition much worse, as the wound became infected and some of the laryngeal cartilages sloughed out. In August the extreme cicatricial stenosis was dilated from below up with urethral sounds and a large intubation tube inserted. This was left undisturbed, with one change in the middle of September, until November. A cure was then obtained, and there has been no relapse since.

I will not go into more particulars as regards this case, as I have reported it in detail before; but it is noticeable that she submitted to two tracheotomies, one of which at least was through the cricoid cartilage, and was performed in extreme haste by an inexperienced man, who had never previously even seen such an operation; yet the œsophagus was not wounded, and there were no infection, no bronchitis, and no pneumonia. The subsequent early resort to intubation undoubtedly prevented the dense cicatricial stenosis so common in such cases. But this resulted afterward from my laryngotomy, and was made worse by the infection and slough of the cartilages. I can only add that the cure obtained by intubation, with large tubes inserted for long periods, seems now to be permanent and perfect.

In this series of seven cases there are four laryngotomies and ten tracheotomies without a death which can be ascribed to the operation. In the majority of instances the tracheotomy was performed under difficulties and in great haste, and yet no serious results followed. The most troublesome problem was the struggling and the anæsthetic to prevent it, and the impossibility of placing the patient in the most convenient and accessible position. The adults suffering from extreme dyspnœa could not breathe at all except while in the sitting or semi-recumbent posture. In two cases ether was foolishly attempted, and owing to the closure of the glottis consequent upon the irritation of the vapor and the struggling (it is probably a combination of both), the operation had to be performed with practically nothing but the sense of touch as a guide. Cocaine in the third adult was a great improvement, and should always be used when the patient is controllable; but children or patients who cannot be kept quiet require chloroform, and in no instance did it cause trouble.

Most of my patients suffered division of the cricoid cartilage, and experience seems to demonstrate that such an operation, if the cannula has to be worn for any length of time, invariably leads to subsequent bad cicatricial contraction, which can be cured only by prolonged intubation. I believe, however, that it can be permanently overcome in every instance, of no matter how long standing, in the manner indicated above.

Laryngotomy, except for tumor, is absolutely useless. The high opening of the respiratory passages, on the other hand, has some distinct elements of safety in its performance. One involuntarily chooses this locality in emergencies, especially in short-necked subjects and in children, and the knife, entering obliquely with the point directed somewhat upward, will be stopped by the broad posterior portion of the cricoid, and thus prevented from wounding the œsophagus. I have several times been conscious of a firm resistance, such as might offer to the further advance of the knife, and believe that it has often prevented serious complications. A low tracheotomy presents only the doubtful advantage of a less probability of subsequent stricture above a long-retained cannula. On the other hand, there is a serious risk of wounding some of the big veins at the upper border of the sternum. I have seen these so dilated in cases of extreme chronic dyspnœa that they were readily palpable. The hemorrhage in any form of tracheotomy is somewhat troublesome, and if a large vein were injured death from asphyxia might occur before the vein could be secured, or by bleeding into the trachea. This, by the way, in ordinary cases, seems to be of surprisingly little moment, and a considerable amount of blood can be aspirated without causing the least harm.

If the stenosis is not chronic, and there is hope of a speedy cure by a simple tracheotomy and the wearing of a cannula a couple of weeks, and also if a careful dissection is possible, the low operation is preferable. But in chronic cases, in which the stenosis must afterward be overcome, and in cicatricial stenosis (in which, by the way, one can practically guarantee a cure with intubation and patience), the low operation is exceedingly troublesome. The lower the fistula the more difficult it is to pass an intubation tube by it, and subsequently to keep the lower end of the instrument from slipping out and catching in the wound. This may readily prove a fatal accident unless skilled assistance is at hand.

In general, and especially for emergencies and for chronic stenosis which must subsequently be treated by intubation, the high operation is safer and better than the low.

Granulations are often heard of as serious dangers in cases of long-retained cannula. They are generally represented as developing in the trachea from the irritation of the tube, and at its withdrawal more or less completely blocking respiration. This complication cannot be common—at any rate, it was not encountered in any of the cases mentioned above, and in several of them the cannula has been worn for quite long periods; in the first case for over four years, with the exception of three comparatively short intervals for in-

tubation. Granulations certainly do develop at the upper angle of a high tracheotomy wound, but do not in themselves give trouble. They are merely a prelude to the subsequent cicatrix, which draws the trachea together in a dome-shaped pouch above the cannula, and this contraction seems to be the worse the nearer the wound is to the vocal cords.

In conclusion, I might remark that it is not always possible to diagnose on the instant the locality of the obstruction, as evidenced in Case IV., but if a short cannula does not relieve the dyspnœa, a long one should be tried, and a stomach tube is a good substitute.

RECURRENT VOMITING OF NERVOUS ORIGIN.[1]

By LOUIS FISCHER, M.D.,

NEW YORK.

Leyden, of Berlin, was the first to describe[2] the condition known as periodical vomiting. He regards this disease as a pure neurosis, and compares it to the gastric manifestation of tabes. The most pronounced symptoms enumerated by him are great abdominal pain, scanty urine, great exhaustion, and absence of fever; his patients were adults. Griffith in a paper presented to the Association of American Physicians, May, 1900, describes four cases of so-called recurrent, or cyclic, vomiting. Some of these attacks, occurring every three to three and a half weeks, appeared without any assignable cause, with no indiscretion of diet and without any symptoms of indigestion. Constipation was always present. In some cases, when the constipation was relieved, the vomiting ceased; in others, in spite of relief of the constipation, the attacks of vomiting continued. This showed that there was no clear association between the relief of the constipation and the cessation of the vomiting. The ratio of uric acid to urea in one of his cases was as 1 : 116.

The vomiting is obstinate, oft repeated, and mucus, as well as bile, is ejected. Frequently an almost pure gastric juice is ejected. The examination of the gastric contents, made with the usual test meal of a cup of tea without sugar or milk, shows an excess of hydrochloric acid—hyperchlorhydria. Leyden believed that the movement of the bowels, which usually followed severe attacks of vomiting, was the result of the vomiting spell.

Griffith reports a retracted or flat abdomen in his series of cases. This is contrary to my own experience, in which there is and has been marked distention of that region.

Thirst is intense, evidently due to the abstraction of liquid from the system, plus the inability to retain any fluid ingested.

Anorexia is usually present. This frequently changes, as in the case reported by me to-night, to hyperorexia. The appearance of the tongue is in marked contrast to that noted in attacks of indigestion. In the latter it is always furred and coated; whereas in this neurotic condition the tongue is clean.

The breath: Rachford, in describing some experience with periodical vomiting, notes a sickening odor—a decided fætor ex ore. Griffith believes this arises from the presence of acetone.

Sore throat was frequently present in my cases, and also the lump in the throat—globus hystericus. The temperature rarely was above normal, the highest temperature noted being 100°, during a persistent constipation.

Respiration was markedly irregular, occasionally sighing, at other times absolutely normal.

The painful affections described by Leyden and Rémond are different from the non-painful variety described by Fenwick, Symes, and Gee. Rachford believes that attacks of vomiting may be due to lithæmia or some condition allied to it, and that there is an absorption and storing up in the system of leucomains. He regards the condition as a lithæmic gastroneurosis, allied to migraine, with toxic substances floating in the blood, not necessarily uric acid but some toxalbumin allied to it.

The following case of a girl about fourteen years of age has been under my care and observation for six years. When she first came to me at the age of eight, she had this history:

Minnie B—— was first brought to the children's service of the German Poliklinik in 1895. She was a breast-fed child, and her nursing lasted two and one-half years—a prolonged period. She walked at about the end of her eighteenth month. Dentition seemed to be rather troublesome, for the mother stated that the child's teeth first appeared when about one year old, and that the patient had convulsions associated with the eruption of each new tooth. She has always been a very delicate child, compared with the other children in her family.

Family history: Both parents are living and in apparent good health. Her mother states that she has had eight children in all; five are living, and three have died—one of diphtheria, another of scrofulosis (probably tuberculosis), and a third of summer complaint.

The mother further stated that she had never miscarried. There is no history of any chronic nervous disease or any affection which could be called a really "neurotic" element in this family.

Previous illness: The patient had the following diseases since birth: Convulsions, as previously stated, during the period of dentition, rachitis, very decidedly owing to improper feeding, and to the prolonged nursing period mentioned in the clinical history. She had a severe attack of variola when about two years old, the evidence of which is still plainly visible on her face.

When the child was eight years old, she was attacked with pertussis extending over a period of nine months, with very violent paroxysms of cough. At this time the child suffered with gastric pains, similar to the kind from which she still suffers, so that her present illness was associated with the whooping-cough, paroxysms of cough ending in vomiting. After the cough subsided, vomiting remained, and although it is six years since the first attack, the symptom at times is very severe. She had measles when she was nine years old, which lasted in all about two weeks, without any noteworthy complication remaining; and she frequently suffered with tonsillitis.

Her menstruation appeared when she was thirteen years old, recurring at regular monthly intervals until about one year ago, when the menses ceased entirely for a period of nine successive months. They reappeared after appropriate treatment with tonics, iron, and, principally, proper food, with improved hygiene. She is quite regular, although she tells me that some months she menstruates but one day. No vicarious menstruation has appeared at any time during the cessation of the regular flow.

Present condition: She continually complains of pain in the stomach, which is not distinctly localized. It is located on the left side more frequently than on her right; also at the epigastrium.

Chemical examination of gastric contents: The continued gastric pain, increasing after the ingestion of food, made the diagnosis of ulcer probable. There

[1] Presented to the section on diseases of children, New York Academy of Medicine, February 14, 1901.

[2] Zeitschrift f. klin. Med., 1882, iv., 605.

are also continual backache, and pains in the extremities. This same condition has lasted uninterruptedly for a period of about six years, during which time therapeutic skill has frequently been vainly tested. The gastric contents have frequently been examined with a test breakfast consisting of a cup of tea and a water roll, no sugar or milk having been added to the tea. On several occasions I have found an excess of HCl, so that a distinct hyperchlorhydria could be diagnosticated. At other times, with the same diagnostic means, a perfectly normal gastric juice was found. To satisfy myself that no error had been committed during the chemical examination of the gastric contents, I referred this patient to Dr. Dauber for a corroborative examination. He confirmed my findings, and added that he believed we could exclude gastric disease in this case, and he further believed that the vomiting was distinctly neurotic in character.

Hyperorexia: An interesting point is that my patient is always hungry and has a distinct hyperorexia.

Vomit: Blood has never been present, although large quantities of mucus have been vomited mixed with the food.

Frequency of vomiting: While the patient has vomited a dozen times during one day, there are many days in which she has vomited but once, and rarely a day with no vomiting at all.

The intestinal canal: The abdomen shows considerable distention, and flatus is common. The bowels seem to be tender on palpation, and constipation has always been a marked symptom. In fact, this patient has had no regular unaided evacuation of her bowels since she has been under treatment, in spite of the fact that nux vomica, gentle faradization, cascara sagrada, malt, and general hygienic measures have been strictly carried out. If the day passed without a movement, I have insisted on an enema being given to relieve the bowels; if necessary, every evening before retiring.

The urine, examined many times, showed the presence of acetone, also of indican. The following is the record of one careful examination made at my request by Dr. J. Henry Wurthman:

Specific gravity 1,026. Urea, 6.24 grains to an ounce of urine. No albumin; no sugar. Indican scanty. Acetone present. Uric acid, excess.

The presence of acetone indicates a disturbance of metabolism, showing a decided toxæmia; but it is well known that acetonuria *per se* does not cause vomiting.

Nervous symptoms: The patient constantly complains of headache, pains, and burning sensations in the eyes, and dizziness also; she is extremely irritable, has bad dreams when asleep, but otherwise suffers with insomnia. She also complains of pains in the back, arms, and legs, and of a general well-marked hyperæsthesia of the skin. She frequently falls in a faint. She has cold extremities in winter and summer.

The skin: The cutaneous circulation is exceedingly poor, and her lips are frequently cyanotic, in spite of energetic friction of the skin, and cold sponge baths.

The mental condition is certainly poor, inasmuch as the patient's memory is bad. She does not care to read, broods about her condition, and, I believe, constantly exaggerates her symptoms, to enlist sympathy. She shows distinct evidences of hysteria minor.

The heart's action is quite feeble. At times there is a slight blowing murmur which can be heard in the vessels of the neck. This is attributed to the general anæmic condition. The pulse has always been feeble and small but regular, with no intermission.

An examination of the blood showed marked leucocytosis. With the hæmoglobinometer (Fleischl), forty-five per cent. was found. The child frequently complains of enuresis and, besides this, of bed wetting; the urine passes from her when she coughs or sneezes.

Treatment: Absolute rest for the stomach has been tried by ordering the child to bed for weeks at one time, and administering ice and ice-cold drinks. All food was ordered thoroughly peptonized and all cereals were dextrinized by adding malt.

When vomiting was most pronounced no food was given per mouth, and rectal feeding of peptonized yolk of egg and of peptonized milk was resorted to. In spite of this method of feeding, some liquid would be vomited, which on examination corresponded to pure gastric juice.

The patient's weakness was such that rectal feeding could not be continued for a very long time. The frequency of the vomiting having lessened, it was deemed most expedient to feed in the regular way, and to give larger doses of bromide continually. Besides, semi-solid diet was ordered, and the patient told to abstain from drinking liquids, like soup, coffee, and water. Coffee and tea and alcoholics were absolutely forbidden, and the child has not been allowed to attend school.

Duration of attacks: This child's condition has seemed to improve under the following therapeutic measures: 1. Lavage, after which she improves for a week or more. 2. Morphine or opium in small doses. 3. Sodium bromide gr. x.–xx., repeated every few hours. 4. Hyoscyamine hydrochlorate gr. $\frac{1}{120}$ per dose, three times a day. Besides, faradization, massage, and cold baths, showers, diet, iron, and general restorative treatment, including hypophosphites and cod-liver oil, have been tried. Rich nitrogenous diet (concentrated foods), rest for stomach with ice locally, and an abdominal support (bandage) have been ordered.

TOBACCO AS A FACTOR IN GLYCOSURIA.

By HEINRICH STERN, Ph.D., M.D.,
NEW YORK.

I have observed that the habitual or excessive use of tobacco is not only apt to aggravate an existing glycosuria, but that it is also—though much less frequently—the causative factor of a glycosuric condition.

I found that tobacco may influence the pre-established pathological output of urinary glucose in the following ways:

First. By protracting the duration of transitory glycosuria, and by imparting to alimentary melliturla a certain degree of chronicity.

Second. By increasing the quantity of dextrose in the twenty-four hours' urine, in the transitory as well as the chronic forms of glycosuria.

Third. By transforming the lighter degrees of chronic glycosuria into the graver forms.

Cases of alimentary glycosuria prolonged by the

excessive employ of tobacco are by no means uncommon. To determine the influence of tobacco in this respect I have repeatedly made the following experiment: An individual with the tendency to alimentary glycosuria, after the complete evacuation of his bladder, is ordered to ingest 150 gm. of dextrose, preferably in the place of his usual midday repast, and to abstain from any work for the rest of the day. The urine for the following six, eight, or more hours is collected separately and examined for glucose. The latter probably appears in the urinary secretion until the sixth, more rarely until the eighth, hour after its ingestion. The same experiment is repeated the next day, but the patient is ordered to smoke at least three or four strong cigars in the afternoon. On this day it will be found that the glycosuria frequently persists for eight, ten, or even more hours.

In an inveterate consumer of tobacco the transitory character of a mellituria may become more or less obliterated or may disappear entirely. I have observed this phenomenon in a number of instances; in some of the cases the modified, transitory glycosuria, on account of its apparent obstinacy, greatly resembled the glycosuria of diabetes.

The diurnal excretion of glucose after indulgence in tobacco may become greatly enlarged.

R. J——, aged forty-nine years, German, banker, has been affected with chronic glycosuria for the past ten years. During this time he has lost about 15 kgm. in body weight. He is a slave to tobacco and has been so since his boyhood; he consumes, on the average, from twenty to twenty-five of the strongest Havana cigars every day. He also partakes of liquors, but in moderation only.

September 12, 1900. Body weight, 77.5 kgm. Urine: specific gravity 1,030; glucose (mean percentage of the twenty-four hours) 2.15 per cent.

After the institution of an exclusive meat-fat diet, the body weight became reduced, but not the glucose output.

October 28, 1900. The patient, still under rigid antiglycosuric regimen, excreted more sugar than he ever did before, viz., 4.75 per cent. The patient, however, asserts that he feels stronger and more energetic than for years, although his body weight has in the mean time fallen to 75 kgm.

October 30, 1900. The patient smoked but six cigars during the last twenty-four hours. The amount of urine voided for that time was 1,850 c.c.; its specific gravity was 1,022, and its content of glucose amounted to 9.6 gm., or about 0.5 per cent.

October 31, 1900. The patient has refrained from smoking since yesterday. Urine: specific gravity, 1,023; glucose, 0.5 per cent.

November 1st. Continued abstinence from tobacco. Urine: specific gravity, 1,023; glucose, 0.75 per cent.

November 2d. Continued abstinence from tobacco. Urine: specific gravity, 1,024; glucose, 0.75 per cent.

November 4th. The patient admitted having smoked about twelve cigars during the day. Urine: specific gravity, 1,030; glucose, two per cent.

November 11th. The patient adheres to the prescribed diet, but smokes excessively, contrary to instructions. Urine: specific gravity, 1,029; glucose, 2.8 per cent.

November 13th. The patient has not smoked on the previous day. In order to point out to him the baneful influence of tobacco upon his glycosuric condition he was induced to smoke but two cigars on this day, shortly after breakfast. 11 A.M. (two hours after consumption of two cigars), urine: specific gravity, 1,028 glucose, 1.5 per cent.)

3 P.M. (six hours after consumption of two cigars), urine: specific gravity, 1,025; glucose, 1.5 per cent.

5 P.M. (eight hours after consumption of two cigars), urine: specific gravity, 1,024; glucose, 0.75 per cent.

8 P.M. (eleven hours after consumption of two cigars), urine: specific gravity, 1,019; glucose absent.

While, as a general rule, the lighter cases of chronic glycosuria are not aggravated by moderate use of tobacco, this substance, when excessively employed, may become a potent factor in the transformation of the lighter into the graver forms of this condition.

S. H——, aged forty-eight years, American, merchant, was affected with glycosuria for three years when he applied to me for treatment in February, 1898. The patient was a moderate smoker, and his glycosuria, although the urine contained occasionally as much as seven per cent. of dextrose, could not be considered one of the graver forms, as it yielded readily when the carbohydrates were excluded from his food, and as 100 gm. of breadstuffs were again well tolerated after two weeks' dieting. Toward the termination of April, more than two months after the glycosuria had totally vanished, there was reappearance of urinary glucose. I could not account at the time for this unusual occurrence, as the patient—for which fact I had ample proof—adhered strictly to the prescribed diet. The contents of sugar in the urine varied between 1.5 and 2.7 per cent., which figures were not lowered even when the patient was put under the most rigid antidiabetic regimen. About a month after the re-establishment of glycosuria, the condition of the patient, whom I saw weekly, became alarming. He had lost almost 8 kgm. of body weight in four weeks; adynamia was present to a very marked degree; his intellect seemed clouded and his memory had materially diminished. The output of carbamid amounted to over four per cent. There could not have been any doubt that the patient was affected with a grave type of diabetes. Closer questioning brought out the fact that the patient, to console himself for his monotonous and unsavory repasts, had used tobacco to a very great extent, and it was found that the reappearance of urinary glucose was synchronous with the first overindulgence in the Indian weed. As the patient would consent to only temporary and partial withdrawal of tobacco, it could never be ascertained whether the glycosuria would be entirely suppressed when the former was totally and permanently banished. The temporary, partial withdrawal of the weed was always followed by a slight improvement of the glycosuria and the other symptoms. Confinement of the patient in a sanatorium did not prevent his obtaining tobacco in any desired quantity. I was finally compelled to decline further treatment of the patient on account of the continuous disregard for my advice and admonitions. He died about nine months later.

The following is another case in which, from a light type, the graver form of diabetes was induced by tobacco:

M. L——, Hungarian Hebrew, aged forty-seven years, consulted me in the spring of 1898. He presented the clinical picture of diabetes. Glucose occurred to the amount of 2.75 per cent. A diet with partial exclusion of carbohydrates reduced the glucose, after one week, to 1.5 per cent., after three weeks to one per cent., and after five weeks to 0.66 per cent. As the patient did not submit to a more rigid diet, the sugar output never declined below the last-named figure. However, in six weeks of partial dieting he had gained almost 6 kgm. in body weight, and the symptoms of diabetes, with the exception of the glycosuria, had subsided. The patient had been for years a moderate smoker: on my advice he had taken a vacation, and finding now more leisure hours at his disposal than in former times, inadvertently began to consume larger and ever-increasing quantities of tobacco. When the patient presented himself a month later, that is, about ten weeks after he first started to diet himself, he had not only lost the previously gained 6 kgm. of body weight but 0.5 kgm. in addition thereto.

The phenomena indicative of diabetes were again exhibited, but in a more aggravated form than ever before. A rigid fat-meat diet was instituted with some beneficial results. The urinary glucose fell from 3.25 per cent. to two per cent. after one week's employment of this regimen, but the patient's weight declined also. The weight became stationary only after the complete withdrawal of tobacco and after four weeks of the strictest dieting. The output of glucose during this time, and for the next eight months, after which period he passed from under my observation, on no occasion declined below one per cent.

These cases stand by no means isolated. I could relate a number of others in which the aggravation of the diabetic symptoms can be definitely traced to the consumption of excessive amounts of tobacco.

The foregoing data tend to illustrate the influence of tobacco upon an already established glycosuria; that tobacconism may be the direct cause of the glycosuric symptom the following case will evidence:

S. L. C——, American, aged fifty-two years, bank president, first consulted me on January 21, 1900. The patient stated that he was a diabetic for two years past; that he had during that time been under the treatment of half a dozen prominent physicians; that he was keeping a rigid antidiabetic diet; that his urine, since the discovery of glycosuria, was never free from sugar; and that, in spite of all the dieting, the sugar output, in absolute figures, was about the same as when he began treatment.

The patient was non-luetic; he had lost about 11 kgm. in body weight; but, with the exception of some nervousness and anxiety, had felt well; his memory had materially weakened and he noticed a gradual decline of sexual desire; he had never suffered from pruritus or any other skin affection, neither was he ever affected with dipsosis or with bulimia. He was not predisposed to affections of the upper air passages nor did he complain of a uric-acidæmic tendency. For some time he had been quite irregular in his habits of living; he had always slept well. An examination of the patient did not disclose any organic abnormality. His weight was 106.5 kgm. The urine showed among other characteristics the following: Amount excreted in twenty-four hours, 2,800 c.c.; acidity, 0.46 per cent.; specific gravity, 1,022 at 15.5° C.; carbamid, 1.8 per cent.; glucose, 1.35 per cent.

In order to determine the influence of the diet upon the glycosuria, the patient was put under a most rigid antidiabetic regimen. After four days his condition was unchanged; the diurnal output of urine, however, had decreased to 2,100 c.c. and its specific gravity to 1,019.5. When the patient presented himself for a second examination he acknowledged his addiction to excessive quantities of extraordinarily strong cigars—eighteen, twenty, or even more during the day. He reluctantly promised to smoke but eight cigars during the following twenty-four hours. Under a liberal diet, one free from sugars but not from other carbohydrates, he did not excrete even a trace of glucose on that day. During the next four days the patient was not restricted at all in his diet, but his daily allowance of cigars was reduced to six. During this period not a particle of glucose made its appearance in the urine. The patient was under observation for another fortnight, during which time he was permitted to partake of everything in the way of ingesta; his moderate use of tobacco during this period was on no occasion followed by glycosuria.

January 9, 1901. The patient is now in the best of health and has gained over 10 kgm. in body weight. He does not and has not put any restriction upon himself as regards his diet. His urine is free from glucose, and he admits that after overindulgence in tobacco he must suffer the penalty—glycosuria.

The literature contains almost nothing concerning the relation of tobacco to glycosuria or diabetes mellitus. Attention is drawn by a few authors to the fact that the excessive use of tobacco exerts a more baneful influence upon the diabetic than upon the healthy individual, and they suggest withdrawal of tobacco from such diabetics in whom certain disorders, as affections of the heart, eyes, and respiratory organs, have ensued.

By no means do I venture to maintain that nicotine poisoning is the causative factor of tobacco glycosuria or of the aggravation of a pre-existing melliturla. The fumes of the burning tobacco leaf contain very little if any nicotine, as this is readily decomposed by the heat. The fumes contain a series of volatile picolin salts, as pyridin, collidin, picolin, and lutidin; they also contain minute quantities of acetic, oxalic, and hydrocyanic acids, carbon monoxide and some other gases.[1]

Nicotism in its chronic and severe form may give rise to certain neuroses and psychoses. Glycosuria or diabetes frequently occurs in the train of disorders of the nervous system. Indirectly, therefore, we could feel tempted to consider nicotine poisoning as an eventual precursor of glycosuria. The etiological relationship of neuroses or psychoses to glycosuria or diabetes, however, is still problematic. Besides, the tobacco neuroses are hardly ever met with in smokers of tobacco; they are almost always the result of excessive chewing of the weed. A coexisting neurosis and glycosuria may arise from a common cause, and the symptom appearing last need not be the consequence of the condition which prevailed first, or they may take their origin from different sources altogether. As, moreover, the neurotic and psychic phenomena in my cases were of such a mild character that I cannot possibly associate them etiologically with the occurrence of glycosuria, I must preclude nicotine as an important factor in the production of tobacco glycosuria. Besides nicotine, the empyreumatic, acrid substances liberated on burning or heating the fermented tobacco leaves may call forth a tobacco toxicosis. As the influence of these empyreumatic compounds upon the animal organism is such a varying one, and as they—in the form in which they are introduced into the body—principally affect the mucous membranes, I also exclude them from any important participation in the causation of tobacco glycosuria.

The most poisonous matter contained in tobacco smoke, the one whose toxicity in this respect has never been fully appreciated, is carbonic oxide gas.[2]

The presence of carbon monoxide in the fumes of tobacco, it being a product of imperfect combustion, is always assured. While the obnoxious influence of nicotine may be successfully combated (without injuring even the good qualities of the tobacco), we have no means of suppressing the formation of carbonic oxide in the burning cigar. The amount of CO evolved is not only dependent upon the quality of the tobacco, upon its degree of moisture and its combustibility, but also upon the mode of manufacture of the cigar and upon the latter's consistency. It stands to reason that the greater bulk of CO evolves from the innermost layer of the cigar, from whence it eventually will unite with the fumes. Much less CO originates from tobacco smoked in pipes. The greater surface exposed to the air and the looseness of the packing permit a more rapid and complete combustion. I have observed tobacco glycosuria only in smokers of cigars and never in those who consume tobacco in pipes exclusively.

[1] Heinrich Stern: "The Toxicity of Tobacco and a Method of Eradicating it." Medical Review of Reviews, April, 1899, and St. Louis Medical and Surgical Journal, May, 1899.

[2] Stern: *Loc. cit.*

Habitual and excessive indulgence in tobacco may induce chronic carbon-monoxide intoxication. Some pathological phenomena commonly ascribed to chronic nicotism, may also be indicative of chronic poisoning from carbonic oxide gas. Nausea, vomiting, gastric catarrh, anorexia, decline in body weight, hemicrania, vertigo, dyspnœa, asthma, paralytiform affections, and some other symptoms may be met with in nicotism as well as in a chronic carbon-monoxide toxicosis.

The subject of chronic CO poisoning from the consumption of tobacco, to my knowledge, has heretofore never been taken into due consideration by toxicologists, medical jurists, and physicians. Nicotism, which is thought synonymous with tobacco intoxication, is but one form of the latter. The CO arising from incomplete combustion of the weed may occasion another seemingly not infrequent form of tobacco intoxication. There may be, as a matter of course, synchronous occurrence of both types of intoxication.

I have not examined the blood of all my cases of tobacco glycosuria for CO. In four instances, out of a total of seven, I found the blood of a decided lighter hue. The blood of two patients, subjected to spectral analysis, did not definitely show the presence of carbon-monoxide hæmoglobin. The blood of one patient reacted positively with Katayuma's test [1] and with NaOH.[2] Katayuma's reagent gave negative results in the other six instances; NaOH demonstrated the presence of CO in two more cases.

It is an established fact that in chronic CO poisoning glucose is very often found in the urine. Hesse and Friedberg[3] were the first to discover mellituria in man, following CO poisoning; after Richardson and Bernard, independently of each other, had observed the same phenomenon in animals some years previously.

The glycosuria of an acute, non-lethal CO intoxication, in almost every instance, is limited in degree as well as in duration. Frerichs in his cases found that the CO glycosuria never persisted longer than for two or three days, and that in but one instance the glucose output lasted four days; he had never seen a case in which the excreted sugar amounted to more than 1.5 per cent. CO poisoning, originating from the continued and excessive use of cigars, persists just as long as its causative factor continues. The glycosurias in the train of this condition, it is evident, may attain a certain degree of chronicity. The intensity of the mellituria in chronic CO intoxication is apparently moderate; in all those instances in which the output of urinary glucose exceeds two or three per cent. we may assume that the CO glycosuria concurs with another mellituric condition.

56 East Seventy-sixth Street.

Ether Narcosis.—W. Reinhard refers a large portion of the post-operative pulmonary troubles, pneumonia, bronchitis, etc., to the often enormous secretion of mucus and saliva produced by the anæsthetic. By the routine use of small doses of atropine, which may advantageously be combined with morphine, given hypodermically three-quarters of an hour to an hour before the anæsthesia is begun, these difficulties may very largely be obviated and the danger of cardiac or respiratory failure also be much diminished.—*Centralblatt f. Chirurgie*, March 16, 1901.

[1] Equal parts of ammonium sulphate and acetic acid, added in very small amounts to blood diluted fifty times with distilled H_2O, will impart to CO blood a bright cherry color; normal blood thus treated, assumes a greenish-gray discoloration which is sometimes tinted with red.

[2] Blood diluted twenty times with distilled H_2O, to which an equal volume of NaOH solution has been added, attains, if normal, a dirty brownish hue; if it contains CO, the mixture will be albescent at first, but become light red later on.

PITYRIASIS VERSICOLOR OF THE FACE.

By WILLIAM S. GOTTHEIL, M.D.,

NEW YORK.

Some time ago I recorded a case of pityriasis versicolor occurring upon the palms; which was unique, since the concurrent testimony of all authorities is to the effect that it never appears in that locality. It is almost the same with the face; the parasitic growth occasionally extends from the chest on to the neck and even to the jaw; but I can find no record of primary infection of the face, and involvement of that part alone. It has been my fortune, however, to meet such a case recently, and under circumstances which might well lead to an erroneous diagnosis.

The patient was a young colored man, in whom the eruption was situated on both cheeks, the right eyelid and temple, and nowhere else upon the body.

It looked like a pure pigment atrophy, one of the leucodermas not uncommon in the dark-skinned races; and this was the diagnosis made at first sight. The spots were dingy white, much lighter than the normal skin, sharply circumscribed, and non-elevated. On the left cheek were several larger affected areas with circinate borders, evidently caused by the coalescence of smaller circular lesions, a number of which were scattered upon the cheek outside. The right cheek was almost entirely occupied by an uncolored patch stretching to the nose, lips, and angle of the jaw, and up on to the temple and right eyelid. Here also there were a few isolated circles. The patient had had the spots for several weeks, and they had been slowly growing in size.

Close examination of the lesions revealed the presence of a slight furfuraceous scaliness, and the scales under the microscope were found to be full of the characteristic microsporon. They could be readily scraped from the surface; yet the patient claimed that he washed his face with soap and water daily.

The points of interest about the case are the appearance of the lesions as circular grayish-white discolorations upon a dark surface, instead of yellowish or

reddish-brown stains upon a light one, and that they appeared upon the face only, where their persistence is as unexplainable as upon the palms, and almost as rare. The grayish-white color was undoubtedly caused by the white scales of epithelium upon the epidermis. The combination of colors of the microsporon and the dark epidermis alone would probably cause a simple darkening of the tissues.

The patient was rapidly cured, of course, by washing the affected area several times daily with 1 : 3,000 solution of bichloride in tincture of green soap.

144 West Forty-eighth Street.

AN EXTREME CASE OF SIMPLE ANÆMIA.

By ROLFE FLOYD, M.D.,
AND
WILLIAM J. GIES, Ph.D.,
NEW YORK.

History.—X——, female, nineteen years old, single, mulatto, waitress, was admitted to Dr. Delafield's service at Roosevelt Hospital, November 13, 1899. Her mother was dead of consumption. She had had no previous illness which could bear on the case. Her health had always been good. In April, 1899, she had been delivered of her first child, at term, in an institution. A normal puerperium followed. She was set to work again as soon as possible. In August she began to feel weak and to suffer from headache and vertigo. About one month later she began to notice dyspnœa on exertion with marked cardiac palpitation, and slight cardiac pain at times. In October a persistent diarrhœa began, of six to eight large, fluid, fecal movements a day, containing no blood or mucus and not associated with tenesmus or colic. Marked anorexia but no vomiting accompanied the diarrhœa. She had to give up work. In November she fainted once and her ankles became moderately œdematous. She continued to nurse the infant till the first week in November. She had not menstruated since her pregnancy.

On admission to the hospital she had almost no red color in her skin or mucous membranes. The moderate pigmentation natural to her race gave the surface of her body a leaden hue, but there was no tendency to a yellow cachectic color. She was poorly nourished but not markedly emaciated. There were no abnormal physical signs over the lungs and no dyspnœa while she was quiet. The heart was normal in size and position, its action weak, rapid, and slightly irregular. There was a hæmic systolic murmur at the apex and one over the second left space. The pulse corresponded to the heart action. The arteries were neither thickened nor contracted. There were no abnormal signs over the abdomen, which was thin and retracted. There was slight œdema of the ankles. The voice was weak, and the general weakness and apathy were very marked indeed. Temperature, 101° F.; pulse, 140; respiration, 36. The urine was acid, pale, clear; s. g. 1.011; it contained no albumin and no sugar. Microscopical examination was negative. Blood: HB., 12 per cent.; R. C., 750,000; W. C., 3,300.

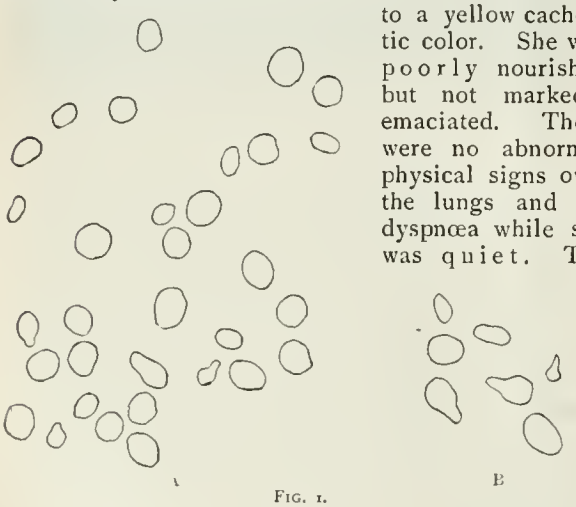

Fig. 1.

The patient was put to bed and given milk and one solid meal a day, which was increased to three meals two weeks later. She was started on gr. xxiv. of sulphate of iron and gr. $\frac{1}{10}$ of arsenious acid in twenty-four hours, and two weeks later the iron was increased to gr. xxxix. A little codeine was given to control the diarrhœa.

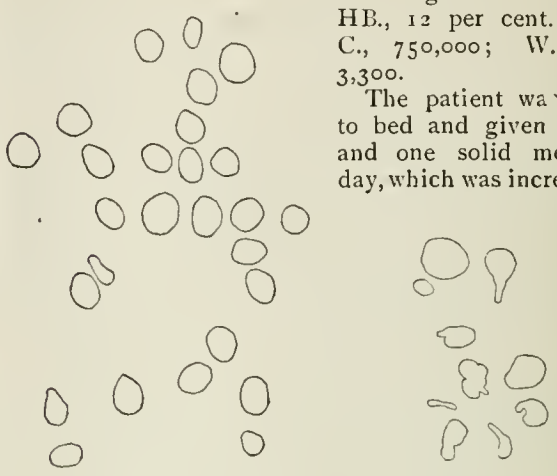

Fig. 2.

During the first week she was in the hospital, her temperature ran between 101° and 103.8°, averaging 102°; during the second week between 98° and 101°, averaging over 100°, and showing a tendency to reach its maximum about noon and its minimum about midnight; during the third week about the same as in the second, the breaks being more pronounced and sustained; during the fourth week between 98° and 100.6°, averaging 99.4°, with the same tendency to rise about noon; during the fifth week it never reached 100°, and after that time it ran a normal course.

The œdema disappeared in a day or two. After ten days' treatment her general strength began to improve. After two weeks her appetite commenced to come back, her voice and pulse grew stronger. Pulse, 90; respiration, 20. At this time, also, the diarrhœa began to yield. During the third week her color began to return and she was able to leave her bed. The changes for the better, once instituted, proceeded with surprising rapidity and she left the hospital, two months after entering it, practically well.

The symptoms, then, which the change in the composition of the blood caused in this case, besides the pallor, were marked general weakness, some headache, syncope, dyspnœa on exertion, cardiac palpitation, disturbed heart action, anorexia, diarrhœa, and œdema of the ankles. The absence of menstruation cannot certainly be attributed to the change in the blood, because of the nursing. It is noteworthy that there was neither bleeding, nor vomiting, nor cachectic color of the skin.

After leaving the hospital she continued to take gr. xv. of sulphate of iron a day for two weeks, and since then she has taken practically no medicine. One month after leaving the hospital she began to menstruate and has been regular ever since. She has been steadily employed for over one year now, and, except for being somewhat prostrated by the extreme heat last summer, has enjoyed perfect health. She was last seen February 5th of this year.

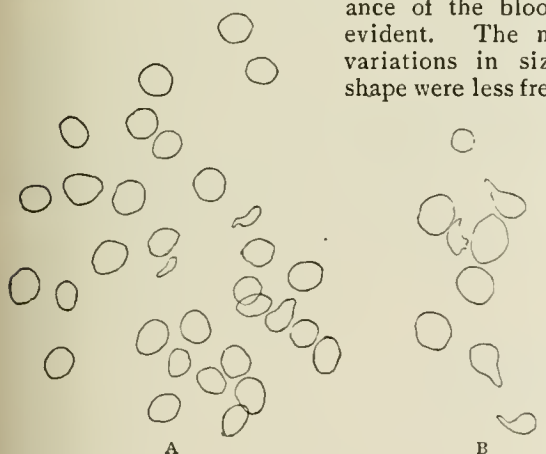
Blood.—The blood was examined once a week during the patient's stay in the hospital, and, after her discharge, at first every two weeks, then every month or two, and latterly at intervals of three or four months. The HB. examinations were made by Fleischl's method.

The outlines of the corpusles were traced with a camera from smeared preparations (A), but, in order to obtain accurate figures of the small and deformed cells, at each of the first eight examinations a few of these were traced from a specimen of fresh blood before crenation had set in (B). Following are the records of each examination:

On admission: HB., 12 per cent.; R. C., 750,000; W. C., 3,300. The red cells varied considerably, but not extremely, both in size and shape. A number of red cells were larger than normal (macrocytes), measuring 10.5 μ in diameter, a number were small and deformed (microcytes). The HB. was moderately unevenly distributed. "Ringing" and extreme pallor of the cells were not present, except in the small deformed cells, at this or any subsequent examination. A very few nucleated red cells (normoblasts) were found. Changes in the coloring matter of the red cells were not observed. The white cells for the most part were normal. A considerable number of degenerating white-cell nuclei were to be seen and an abnormally large percentage of small mononuclear leucocytes (over thirty per cent.) were present, a feature which obtained in the first seven examinations, *i.e.*, as long as the differential counts were continued. There were no excess of eosinophiles and no myelocytes at that time or later (Fig. 1).

Second week: HB., 18 per cent.; R. C., 645,300; W. C., 4,200. The appearances were identical with those above described.

Third week: HB., 25 per cent.; R. C., 1,016,000; W. C., 5,600. A distinct improvement in the appearance of the blood was evident. The marked variations in size and shape were less frequent,



A B

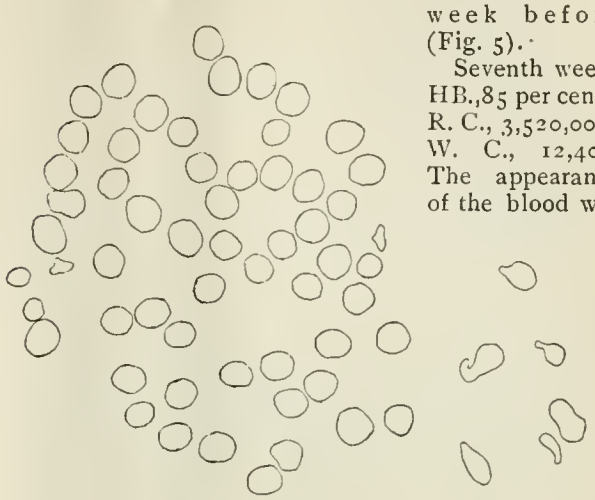
Fig. 3.

the moderate variations were still universal, and there were still a number of macrocytes. The HB. was more evenly distributed. One nucleated red cell (normoblast) was found. The white cells were practically normal (Fig. 2).

Fourth week: HB., 45 per cent.; R. C., 1,568,000; W. C., 5,600. The universal variation in size and shape was less marked, but the considerable variation of a certain number of cells persisted, dividing the red cells more or less into two classes. The HB. was pretty evenly distributed except in the small and deformed cells in which it was irregular and often deficient. The tendency to form macrocytes was less pronounced (Fig. 3).

Fifth week: HB., 58 per cent.; R. C., 2,556,000; W. C., 9,200. The universal change in shape and size was distinctly less than at the preceding examination. Marked variation in size and shape persisted in a small number of cells, and a pretty strict division of the red cells into two classes could at this time be made. The macrocytes had practically disappeared. HB. was evenly distributed in all the cells except the small and deformed ones (Fig. 4).

Sixth week: HB., 66 per cent.; R. C., 2,900,000; W. C., 11,800. The great majority of the cells had nearly reached the normal limits of variation in size and shape. Every here and there a markedly deformed and small cell was still to be seen. HB. as week before (Fig. 5).



A B

Fig. 4.

Seventh week: HB.,85 per cent.; R. C., 3,520,000; W. C., 12,400. The appearance of the blood was practically as in the sixth week, except that the general appearance of the cells was slightly more even (Fig. 6).

Eighth week: HB., 90 per cent.; R. C., 3,556,000; W. C., 11,400. The appearance of the blood was now normal except for the small and deformed cells usually deficient in HB., which could be found in every second or third field (Fig. 7).

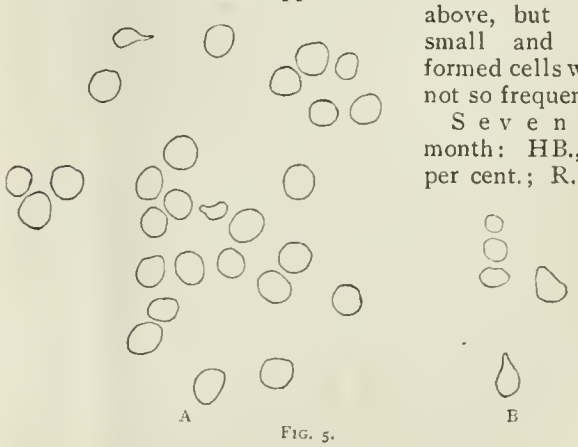
Ninth week: HB., 97 per cent.; R. C., 3,796,000; W. C., 7,000. The appearance was the same as at the eighth week, but the variation in size and shape of the small cells was not so marked. Just after this examination the patient left the hospital.

Eleventh week: HB., 78 per cent.; R. C., 3,500,000; W. C., 10,200. The general appearance of the blood still fell within the normal limits of size and shape variation, but there was slightly more variation than two weeks before. The small and deformed cells were seen in every third or fourth field (Fig. 8).

Thirteenth week: HB., 82 per cent.; R. C., 3,786,000; W. C., 5,000. The appearance was the same as at the preceding examination.

Fourth month: HB., 76 per cent.; R. C., 4,592,000; W. C., 7,200. The appearance was the same as at the last preceding examination. Small and deformed cells were still present.

Sixth month: HB., 87 per cent.; R. C., 4,496,000; W. C., 8,200. The appearance was the same as above, but the small and deformed cells were not so frequent.



A B

Fig. 5.

Seventh month: HB., 77 per cent.; R. C., 4,712,000; W. C., 9,000. The variation in size was still within but close to the normal limits; the shape was regular. Small and deformed cells were growing still less frequent.

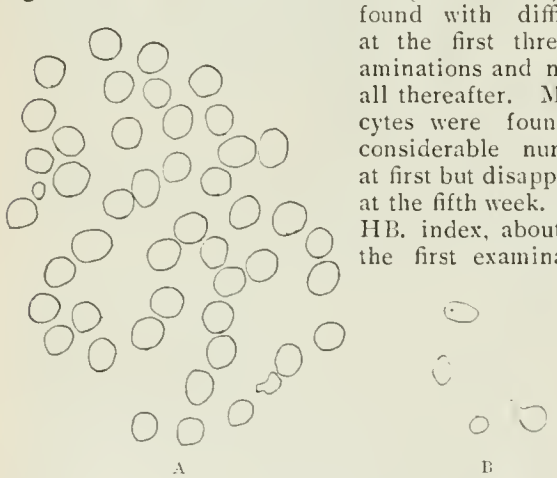
Eighth month: HB., 80 per cent.; R. C., 4,800,000.

The cells had grown a little more regular in shape. The small and deformed cells had practically disappeared—one or two were found (Fig. 9).

Eleventh month: HB., 73 per cent.; R. C., 4,196,000; W. C., 5,800. The variation in shape was again within but close to the normal limit. One small and deformed cell was found after considerable search.

Fifteenth month: HB., 70 per cent.; R. C., 4,712,000; W. C., 6,800. The variation in size had again become less. No small and deformed cells were found (Fig. 10).

In the above set of observations the following features are noteworthy: Starting with about the most depleted condition that is compatible with life, the blood, under a maximum dosage of gr. xxxix. of ferrous sulphate and gr. $\frac{1}{10}$ of arsenious acid in a day, passed to a condition approximating the normal, with a subsidence of all the symptoms in a period of seven weeks. Then, the treatment being entirely suspended a little later, the blood continued in about the same condition for one year and one month after convalescence had been established. The variation in size and shape of the cells, at first very marked though not extreme, steadily diminished until the normal limits were reached at the eighth week, never again to be transgressed. An inconsiderable and diminishing number of the cells, however, continued to be small and deformed as late as the eighth month. Nucleated red cells (normoblasts) were found with difficulty at the first three examinations and not at all thereafter. Macrocytes were found in considerable numbers at first but disappeared at the fifth week. The HB. index, about 1 at the first examination,



A B

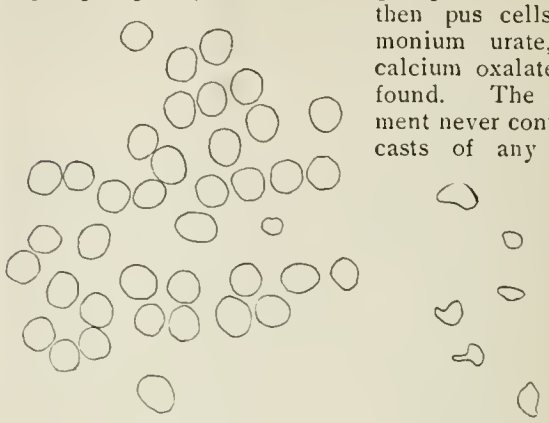
Fig. 6.

increased till it was a little over 1 and remained so throughout the active period of convalescence. It then fell slightly below 1 and stayed there. The absence of "ringing" and pallor of the cells was therefore to be expected. Both the HB. and the number of red cells reached the full normal limit but at different times. The white cells, reduced in number at first, rose distinctly above the normal count at the seventh week, then fell again to normal and remained there. No myelocytes were seen. The accompanying chart will make some of these points more clear.

The case is classed as simple anæmia because of the rapidity and degree of the recovery. The age, the medication—almost exclusively ferrous sulphate—the absence of cachexia, the continued absence of all symptoms without treatment, are corroborative points of interest. It is not unlikely that the patient is now tending toward a relapse of moderate severity as is frequent in simple anæmia.

Urine and Fæces.—Our chemical examination of the urine and fæces gave us the following data[1]:

Urine: The urine varied in color from a very pale to a deep golden yellow. Several samples were more highly colored than normally. The reaction was usually alkaline; once or twice amphoteric (litmus). A slight sediment settled out in each twenty-four hours' urine. This usually contained epithelial cells, triple phosphate, and calcium phosphate; now and then pus cells, ammonium urate, and calcium oxalate were found. The sediment never contained casts of any kind.



A B

Fig. 7.

The specific gravity ranged from 1.011 to 1.019. Once it was 1.022. The volume for twenty-four hours varied between 515 c.c. and 1,011 c.c.

The following substances were invariably absent[1]: coagulable proteid, proteose, dextrose, leucin, tyrosin, lactic acid, diacetic acid, oxybutyric acid, hæmoglobin, cholesterin, acetone, ptomains, and bile salts.

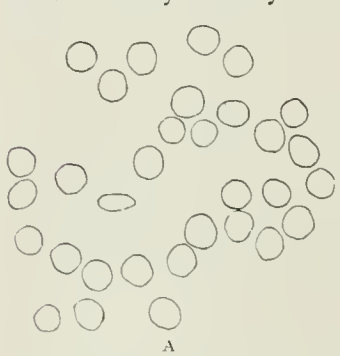
The substances present in each sample, in quantities approximately equal to normal amounts, were: urea, uric acid, chlorides, phosphates, sulphates, indican, creatinin, alloxuric bases, oxalic acid, phenol, and nucleo-albumin (mucin).

Several samples contained unusual amounts of uroerythrin. Each of these contained bile pigment also, but no bile salts. Urobilin appeared to be markedly increased in some of the urines.

The following table presents the results of a few quantitative analyses of twenty-four hours' urine passed during three successive days during the second week:

	First Day.	Second Day.	Third Day.
Urea	18.500 gm.	23.600 gm.	19.800 gm.
Uric acid	.481 "	.527 "	.613 "
Alloxuric bases	.066 "	.093 "	.080 "
Ratio, uric acid to urea	1 : 38.5	1 : 44.8	1 : 32.3
Ratio, alloxuric bases to uric acid	1 : 7.2	1 : 5.6	1 : 7.7
Volume	680 c.c.	884 c.c.	862 c.c.

Fæces: Several daily portions were completely fluid. Usually the daily mixed fæces were partly fluid and partly solid. The odor was always very strong, those of aromatic bodies and fatty acids predominating. A few samples were yellowish in color; usually they were greenish-gray to greenish-black. The more solid portions were never homogeneous, varying much in color and composition. Small mucous clots were contained from time to time. The reaction was always alkaline.



A

Fig. 8.

The solid matter, examined under the microscope, contained starch granules, muscle fibres, connective-

[1] Analyses of urine and fæces were made daily during the first four weeks, in the department of physiological chemistry of Columbia University, at the College of Physicians and Surgeons.

[1] In all of our chemical tests, on both urine and fæces, we employed the methods our own experience and the work of others have shown are the most satisfactory.

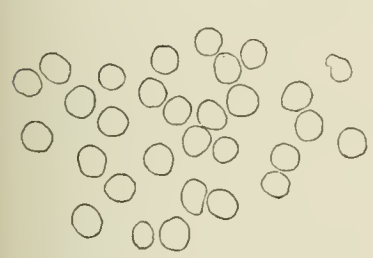
tissue fibres, fat droplets, pigmented particles (yellow), epithelial cells, triple phosphate, soap crystals, calcium phosphate, and myriads of bacteria.

We were unable at any time to find albumin, peptone, proteose, urea, ptomains, blood corpuscles, Charcot-Leyden crystals, hæmatoidin crystals, or cholesterin in crystalline form.

The following substances, in dissolved form, were readily identified, however, by the usual methods, some only occasionally: cholesterin, bile salts, fatty acids, indol, skatol, phenol, tyrosin, alloxuric bases, stercobilin, hydrobilirubin, nucleo-albumin (mucin), and bile pigment.

A review of the chemical data of this case brings out the fact clearly that little was found which may be attributed to any single line of metabolic disturbance—practically nothing that may be said to be peculiar to the anæmic condition.

The specific gravity of the urine was low, its color usually pale, and the volume somewhat less than the average, yet the fluctuations were mostly within the normal limits. The sediment contained nothing of special significance. The amount of urea was low, that of uric acid and alloxuric bases at, or somewhat above, normal; but the ratios of urea to uric acid, and of uric acid to alloxuric bases were within the customary fluctuations. Chlorides, phosphates, and sulphates appeared to be relatively as great in amount as urea. Deductions from our quantitative results cannot be very accurate, however, since it was impossible in this instance to regulate satisfactorily the quantity and character of the patient's food.

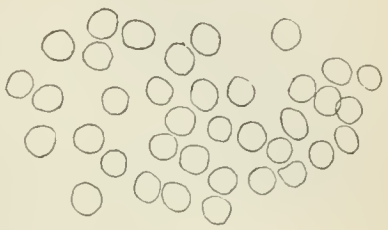


A

Fig. 9.

Albuminuria of hæmic origin was suspected in view of the fact that albumin has been eliminated in the urine during anæmia, but coagulable proteid could not be detected at any time. The uroerythrin we found several times, along with a little bile pigment, and the increased urobilin in some of the urines, rather suggest that the normal pigment metabolism was somewhat disordered, but as the first two substances were present only a few times, little importance can be attached to their occurrence. Although ptomains, putrescin particularly, have been found in the urine during pernicious anæmia, they were entirely absent in this case. The absence of lactic acid is also noteworthy, several observers having assumed it to be a constant constituent of the urine in pernicious anæmia.

There appeared to be little of special significance in the composition of the fæces.



A

Fig. 10.

These results are valuable, we think, chiefly because of their negative character, and we are inclined to believe that, up to the present, few if any special chemical qualities of the excreta have been definitely established as pathognomonic of the various anæmic conditions. Unfortunately, practically all of the work of the past in this direction has been of a very fragmentary character; the results differ widely, and most of them have been recorded with little regard for such influences modifying the usual course of metabolism as the quantity, character, and composition of the food; various secondary pathological conditions; to say nothing of other incidental factors of importance.[1]

A Compared Case of Pernicious Anæmia.—In connection with this case we wish briefly to call attention to another. A woman, sixty-four years old, had been gradually losing strength but not flesh, and getting pale and sallow for one year. She had grown much more rapidly worse for two months. She presented marked anorexia, no vomiting, constipation, no pulmonary or cardiac symptoms, no evidence of bleeding anywhere. When admitted to the hospital she was well nourished, but very pale and sallow. Her lungs were normal. Her heart was normal in size and position; its sounds were very weak, its action was slightly irregular, the pulse corresponding. Artery was normal. No abnormal signs were elicited over the abdomen. Slight œdema of the ankles was present. The voice was very weak. Extreme general prostration was evident. Temperature, 99.4° F.; pulse, 76; respiration, 28. The urine was acid, s. g. 1.012, with a considerable trace of albumin and a few hyaline casts.

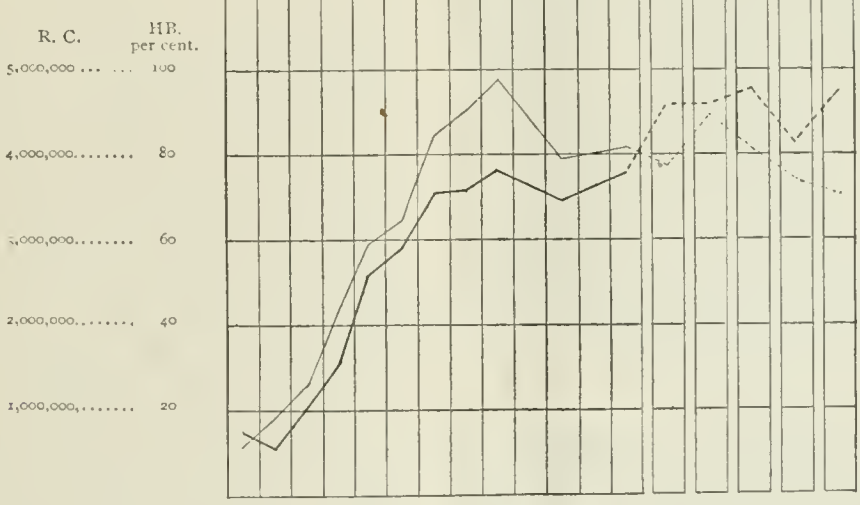


Fig. 11.—Chart to Show the Weekly Changes in the Blood and its Condition at Longer Intervals after the Thirteenth Week. Light line, hæmoglobin; heavy line, red cells.

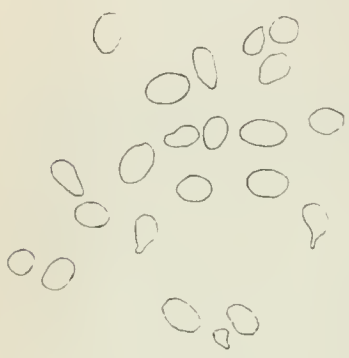
[1] We are indebted to Dr. William A. Taltavall for the following facts: He examined the urine and fæces in three cases of pernicious anæmia; putrescin and cadaverin were invariably absent; urobilin was not increased; uric acid and nuclein bases appeared to be diminished somewhat. The latter consisted mostly of hypoxanthin.

Blood: HB., 22 per cent.; R. C., 756,000; W. C., 4,800. The red cells varied considerably, but not extremely, both in size and shape. There was some tendency to the formation of macrocytes. A moderate number of small deformed cells were present. The HB. was fairly even in most of the cells, but often very deficient in the small ones. One normoblast was found after prolonged search, but no megaloblast. The HB. index was somewhat over 1. There was nothing abnormal about the white cells. No myelocytes were found (Fig. 12).

The patient was put on fluid diet and given gr. xx. of ferrous sulphate, gr. $\frac{1}{4}$ of arsenious acid, and ʒ ii. of carnogen every day. Anorexia and vomiting began very soon. Attacks of syncope occurred. She grew steadily weaker and became restless. The temperature rose over 100° F. only on the last two days of her illness. Death occurred at the end of one week from asthenia.



A

Fig. 2.

The blood on the day before death was HB., 16 per cent.; R. C., 576,000. The appearance of the blood was in no way changed from that of the week before. Although no autopsy was held, the case was considered clinically typical pernicious anæmia.

The similarity of the blood in the two cases is striking and the clinical features also are very similar, with the following exceptions: the age—nineteen in the first case, sixty-four in the second; the absence of the cachectic color in the first case, its marked occurrence in the second; the rapid and complete response to treatment in the first case, and its complete absence in the second.

The above comparison seems to demonstrate that even the crude division of primary anæmias into simple and pernicious cannot be made, especially in severe blood lesions, by the examination of the blood alone, but that clinical features must weigh equally with it in establishing a diagnosis. We believe that to obtain a satisfactory classification of anæmias it will be necessary, besides counting and studying the peripheral blood, (1) to understand the life history of the blood cells, which can be accomplished only through study of the physiology and pathology of the blood-making and blood-destroying organs; (2) to investigate more thoroughly the interrelations between the normal and diseased processes occurring in the blood and those occurring in the other body tissues; (3) carefully to correlate the results of such studies with those obtained by clinical experience.

Experimental Researches in Sero-Therapy in Tetanus.—Guido Tizzoni submits a long list of experiments from which he concludes that the serum prepared by him has a real value in tetanus, and that, moreover, it is superior to the other better-known preparations, including that of Behring. He gives in full the conditions under which the curative substances of the serum are produced, and the reasons for the difference in value between the various kinds. His serum, being in the market, can be easily obtained, and investigators can convince themselves of its superiority by experiments on animals, and by its clinical use.—*La Riforma Medica*, March 12–18, 1901.

ALBUMINURIC RETINITIS IN PREGNANCY; PREMATURE LABOR; DEATH IN UTERO OF TWIN CHILD; PUERPERAL CONVULSIONS; HEMIPLEGIA; ACUTE MANIA; DEATH.[1]

By JOSEPH N. STUDY, M.D.,

CAMBRIDGE CITY, IND.

Albuminuric retinitis in pregnant women is, if we can judge its frequency of occurrence from the literature upon the subject, a rather rare affection. The standard texts upon obstetrics and upon the eye say but little upon this condition. In 1888, Dr. Thomas R. Pooley, of New York, read a paper before the New York Academy of Medicine upon the topic, "Induction of Premature Labor in Amaurosis and Amblyopia with Albuminuria of Pregnancy to Prevent Blindness." In this paper cases are cited in which premature labor was induced and the eyesight generally more or less improved. In 1894, Dr. Herman read a paper before the London Obstetrical Society upon the treatment of severe albuminuria in pregnancy and its relation to blindness and other consequences.

The induction of premature labor was advocated as the proper treatment in such a condition, and in the discussion which followed was generally approved of. Dr. W. O. Moore, in the *Post-Graduate*, July, 1900, says: "These changes in the retina are not of an inflammatory nature, but rather a tissue metamorphosis which produces permanent changes brought about by effete material in the circulatory system, and should be eliminated by the kidneys."

This material may be urea, alone or in combination with other excrementitious substance. Dr. Moore says the prognostic significance is bad when this retinal change occurs, death, as a rule, following within two years. It is an established principle that there are two conditions in which the induction of premature labor is justifiable, to save either the life of the mother or that of the child. In this condition the life of the mother may be lost and that of the child also. Should the mother survive, partial or complete blindness is only too sure to follow. It is certainly true that Nature, in her wisdom to do things well, in a small percentage of cases terminates the pregnancy by miscarriage or premature labor. Too frequently, however, this is too late to remedy the condition that proves so disastrous.

It is believed that the following case presents sufficiently well the above subject:

Mrs. F——, aged forty-two years, American, mother of two children, the youngest of which was fourteen years old. Her previous health was good, excepting a severe attack of typhoid fever seven years ago. She never had any miscarriage, and never had syphilis. Her menses were regular till December 15, 1899.

At the third month of her pregnancy, albumin (five per cent.) was found in her urine. At the fourth month the albumin had increased to ten per cent., and she was passing four hundred grains of urea in twenty-four hours. She was now complaining of much difficulty in seeing; vision in either eye was $\frac{10}{80}$, and constant pain was felt behind the eyes. Her condition did not improve at any time, but gradually became worse. At the seventh month the albumin had increased to fifteen per cent., and she was passing less than three hundred grains of urea in twenty-four hours. She could not see houses across the street, and could not distinguish her husband from others in her presence.

On August 8th, at 8 P.M., without warning, her labor came on. Within ten minutes a premature male child was born, weighing four pounds, which now, at six months, is developing into a strong child. Within fifteen minutes from the birth of the first child a second

[1] Read before the Wayne County (Ind.) Medical Society.

male child, which measured thirteen inches in length, was born dead. Its head and body were well attened, and it had probably been dead for two months. There was one placenta. Eight hours after the birth of the last child she had a hard convulsion, which was followed soon by a second one, more severe than the first one. She was partially unconscious for six hours. Her lying-in period was uneventful. At the end of two weeks she was up, and did the greater part of her household duties for the ensuing five weeks. She gained in flesh and nursed her child, and her vision had greatly improved, being equal to $\frac{60}{80}$ in either eye. Albumin in her urine had decreased to five per cent. There was no swelling of her feet or ankles at any time, and at this period she was thought to be doing fairly well.

She now suddenly became partially hemiplegic in the right arm and leg. She could not walk, and her speech was very much impaired. The tongue, when extended, protruded to the paralyzed side. Her body exhaled an offensive uræmic odor. Albumin appeared in her urine to the amount of twenty per cent., and she was passing two hundred grains of urea in twenty-four hours. Constant pain behind the eyes and in the occipital region and down the neck was now greatly complained of. The vision now became bad; she could not distinguish individuals. She remained in this condition for one week, when she became violently maniacal; it was with much difficulty she could be kept on the bed. She remained in this condition for nearly four weeks, when death from exhaustion ended the scene, November 4th.

Soon after the symptoms of impaired sight appeared, I wrote to Prof. T. A. Reamy, of Cincinnati, in regard to the condition of my patient. He kindly replied that, unless induced labor was immediately done at all hazards, he feared that partial or complete blindness would be the result. This information was imparted to the afflicted woman, but she chose to let nature take its course.

This line of reasoning seems to be based on sound principles, and in such a case labor had better be brought on as soon as vision becomes at all impaired. Otherwise the most disastrous consequences are likely to follow.

Report of Three Cases Bearing on the Subject of Ovarian Hydrocele.—Reed Burns reports three cases which lend proof to Sutton's views that the so-called tubo-ovarian cysts are cases in which the ovary and distal end of the tube have been shut in by adhesion into an unusually deep ovarian fossa, the space so formed and its communicating tube having become distended with fluid, and that they should be called ovarian hydrocele. These cases reported are not cases of tubo-ovarian cyst, nor strictly ovarian hydroceles, but they show that the ovary may be shut up in a hermetically sealed pocket on the posterior side of the broad ligament, without the distal end of the tube being included. In operating in such a case, the condition is recognized by sweeping the fingers over the posterior surface of the broad ligament, where no ovary is found, but instead a more or less elastic spot is felt in the ligament. This should at once make us think of an imprisoned ovary. A ligature should be thrown around the tissues containing the ovarian artery on the pelvic side, and another around the artery and tube close to the uterus, the tissues over the ovary should be split and the ovary and tube removed.—*Pennsylvania Medical Journal*, March, 1901.

Have We a New Treatment for General Septic Infection?—V. Telberg-Hofman gives the histories of a series of septic cases in which sterile oil of turpentine was injected hypodermically, with the most gratifying results. The plan is that advocated by Fochier, of Lyons, who styles it "the production of an artificial suppuration." There are, says Fochier, cases of puerperal fever, for instance, in which we have a general infection improving suddenly, at the same time that a local suppuration has appeared. These local suppurations are, for instance, a phlegmon of the breast, of the iliac fossa, of the subcutaneous tissue; or a monoarthritis, a slow localized peritonitis, or a salpingo-ovaritis. Then, again, there are other cases in which there are undoubted symptoms of visceral inflammations, and these inflammations diminish in severity without there being any improvement in the general condition of the patient. A diffuse subcutaneous phlegmon has a tendency to become circumscribed and suppurate without ever reaching this result, and often death arrives before suppuration has taken place. The injection of turpentine is not more painful than an injection of morphine. The signs of inflammation appear very soon, from one to six hours later, and in some cases it may be necessary to administer an anodyne for the pain, which, however, is very slight or absent when the hypodermic needle is well introduced in a cushion of adipose tissue. Other signs, as redness of the skin, may appear on the third day or later if the injection is made deeper. There are two forms of suppurations caused by the injection of the turpentine, namely, the anthrax form, in which there is a formation of acne pustules under the epidermis, and here the pus is let out through more than one channel; or there is an abscess that has to be opened to give the pus an outlet. As to the frequency of making the injection, one should be guided by the severity of the case. Fochier seldom makes more than two injections of from ℥ xv.–xxv. in one case; while Thierry not only injects every other day, but keeps up the suppuration by irritation of the wound.—*Charlotte Medical Journal*, March, 1901.

Acute Appendicitis Complicating Hernia in a very Young Infant.—J. M. Elder has successfully operated on a child of seven months, who had a scrotal hernia which became inflamed and strangulated. When the child was brought to the hospital, examination showed the right side of the scrotum much swollen and œdematous, and containing a sausage-shaped mass extending up to the external abdominal ring. The child had a temperature of 102° F., a weak, rapid pulse, was very much distressed, and vomited constantly. The abdomen was very tense. Under chloroform anæsthesia, an attempt was made to reduce the hernial mass but failed completely, fortunately for the child, as the sequel will show. An incision was at once made through the scrotal tissues down on the incarcerated bowel. When the tunica vaginalis was opened, free pus was found, and it was thought that the bowel had become gangrenous and was perforated. When the incision was prolonged up to, but not through, the external abdominal ring, it was seen that the strangulated bowel consisted of the cæcum and vermiform appendix, and that the latter had become gangrenous and had perforated, presenting exactly the picture so familiar in the abdomen. The appendix was ligated off in the usual way and the strangulated cæcum and the surrounding tunica vaginalis were then disinfected by swabbing with pure carbolic acid neutralized for a few minutes or so with absolute alcohol. Attention was next directed to the point of strangulation —the external abdominal ring—and the diverging fibres of the external oblique muscle were carefully slit up, until the ring was sufficiently enlarged to permit of pulling down the bowel through the opening. Having thus satisfied himself that the bowel above the ring was not gangrenous, and that the circulation in the part previously strangulated was being well restored, the

operator returned the whole of the strangulated mass, including, of course, the stumps of the appendix, into the abdominal cavity, repaired the ring, and closed the funicular process with buried catgut sutures. The skin incision was then closed by a continuous silk suture, except a small opening at the upper part, through which a narrow gauze drain was inserted. The suture line was then covered by iodoform pigment, and a layer of sterilized absorbent cotton held in place by a spica bandage completed the dressings. The patient made a complete recovery.—*Montreal Medical Journal*, March, 1901.

Compulsory Notification of Tuberculosis.—Sir Charles A. Cameron thinks that the objections to notification would not hold. The sanitary authorities would surely not regard a consumptive as they would a person suffering from smallpox or scarlet fever. They would not be prosecuted for appearing in public. If notification were compulsory, useful information could be supplied verbally or by leaflets to patients and their families, receptacles for sputa and materials for disinfecting could be supplied to the poor by the sanitary authorities, and rooms recently vacated by consumptives would be disinfected before they were reoccupied. As to the proper time to notify, that should be when the physical signs of phthisis are unmistakably present, or when the bacilli of tuberculosis have been detected.—*Medical Press and Circular*, March 20, 1901.

Urea and Nutritive Exchanges in the Child.—Albano Bonfà concludes from experimentation that in children the elimination of urea per kilogram gradually decreases with age, but remains considerably higher than in the adult, being from 1.363–0.539 gm., while in the adult it is only 0.453 gm. The total daily elimination of urea remains almost constant from the second to the tenth year of life, being about 8.5 to 10.5 gm., as against 21.5 gm. in the adult. Diuresis is greatest in the early years and more than double that of the adult. The activity of the nutritive exchanges in children varies in inverse proportion to the weight. The weight of a child's body varies in proportion to the consumption of nitrogenous matters. In infants suffering from gastro-enteric catarrh, there is apparently less consumption of nitrogen. Fever has a marked influence on the nutritive exchanges in the child, the percentage of urea as well as its actual amount being markedly increased.—*La Riforma Medica*, March 8, 1901.

Puerperal Insanity.—In the course of a general discussion of this subject, G. H. Savage calls attention to the fact that now and then a woman will break down after the birth of, say, boys only, or after the birth of girls only, and extraordinary or insane longings have been met with, which have been associated with pregnancy with one sex and not with the other. Another important thing to remember is that the general prognosis of nervous cases is bad when the physical health improves without a corresponding restoration of the mental functions; that is to say, when the mental and physical gains do not coincide. A certain proportion of these cases of puerperal insanity are never the same again; that is to say, they are mentally crippled. It is well to remember that a certain number of these patients are crippled so long as they are in the hospital, and when sent out they get all right again. Sometimes it requires this course, the restoration to home, to shake up, so to say, the machinery, to set the works going normally, and therefore it is frequently recommended that patients who are not quite well should be removed from the asylum, because they have been in it long enough.—*Medical Press and Circular*, March 27, 1901.

Primary Splenomegaly.—Guido Banti states that there is a group of primary diseases of the spleen, of various morbid types, but all characterized by enlargement of the organ and impairment of its functions. In splenomedullary leukæmia, an abnormal quantity of leucocytes is manufactured and poured into the circulation; in the other forms of splenomegaly, certain toxic substances are elaborated, which act upon the red blood cells. A general anæmia is produced, with a steatogenous action on the liver. As to the production of cirrhosis there exists a difference of opinion. The author's experiments have proved conclusively that there are cases of atrophic cirrhosis of the liver of splenic portal origin, but that is not to say that every case of splenomegaly is capable of determining hepatic cirrhosis.—*La Riforma Medica*, March 1, 2, 4, and 5, 1901.

Abdominal Tumor in an Infant.—J. Garland Sherrill reports the case of a child of eleven months, in whom there has been an enlargement of the abdomen for three months. Upon examination the abdomen is found to be considerably distended, and, on percussion, dulness is found on the left side, extending from beneath the ribs down to the level of the anterior superior spinous process. On the right side, about the margin of the ribs, where we should expect to find the normal hepatic dulness, no such dulness is discovered; there is some tenderness about the abdomen, and on manipulation we can feel the margin of a tumor which, on the left side, reaches down below the level of the anterior spine; there is a sharply defined margin to the growth, and the author considers the tumor to be a misplaced liver. If the liver were in its proper place, we should probably say that the case was one of sarcoma.—*Pediatrics*, April 1, 1901.

Cerebral Abscess in a Child of Sixteen Months.—F. E. Bunts reports the case of a child aged sixteen months, who, about six weeks before coming under observation, had received a scalp wound from a piece of tin. No particular attention was paid to the matter, and various applications were made, but the wound did not heal. Three days before the first visit the child had had a convulsion, and it was noticed when it was examined that there was a slight paralysis of the right arm and leg. The latter increased and involved the same side of the face. The knee jerk was easily elicited, though it was difficult to get a reflex at the elbow. The question of diagnosis rested chiefly between the possibility of its being an infantile paralysis, or a paralysis due to abscess of the brain following a septic infection of the scalp. The symptoms persisting, it was decided to operate, and, the scalp having been laid back, a fissured fracture of the skull was found with a portion of the bone penetrating the dura and also the cortical substance of the brain. There was also some bulging of the brain substance. A grooved director was inserted into the brain in various directions without at first discovering any pus, the presumptive point of puncture being about the region of the leg centre. In view of the fact, however, that the paralysis of the leg had slightly improved while the paralysis of the arm had become practically complete, and that the facial muscles were now involved, it seemed probable that a deeper puncture might reveal the abscess. This was done, and about an ounce of pus was evacuated. The patient did well for a while, but finally died at the end of two weeks. The autopsy showed the dura to be tightly adherent to the bone, and the brain to be very soft. Pus was found in various parts of the brain, and it had gravitated down as far as the foramen magnum. The pus found at the base of the brain showed a pure culture of streptococci. —*Cleveland Journal of Medicine*, April, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM WOOD & CO., 51 Fifth Avenue.

New York, April 27, 1901.

THE DIAGNOSIS OF CARCINOMA OF THE STOMACH.

IT seems a dull iteration to emphasize the fact that there are few if any pathognomonic signs of disease. The careful clinician does not base his opinion upon one, or even upon several, but upon all of the phenomena that may be present in a given case, and these he endeavors to group in their proper relations, so as to make as nearly as possible a complete and comprehensive clinical picture. The diagnostic problem is often a most obscure and difficult one, and this is particularly so with regard to abdominal diseases. The desirability of promptness in diagnosis is most marked with reference to malignant disease, especially of the abdominal viscera, because only early extirpation may give relief. In the case of carcinoma of the stomach, for instance, to wait until a tumor is demonstrable is often to permit the time to pass when the best results can be hoped for from surgical intervention. Several symptoms have in late years been thought to possess diagnostic significance in this connection. Thus the absence of hydrochloric acid in the gastric juice was believed to point unequivocally to the presence of gastric carcinoma, but this evidence was soon found to be only of relative and not of absolute value. Then, the presence of lactic acid and of the lactic-acid bacillus was considered diagnostic.

Recently it has been pointed out that the leucocytosis that occurs generally after a meal fails to appear in the presence of carcinoma of the stomach. This, however, is opposed by observations that have still more recently been reported, to the effect that, in addition to the reduction in the percentage of hæmoglobin and in the number of red corpuscles, the colorless corpuscles also, especially the uninuclear, are increased. It has further been said that absence of digestion leucocytosis occurs likewise, though with less constancy, in cases of chronic gastric catarrh and of gastric ulcer. In order to reach an independent conclusion in this matter, Dr. Carstairs Douglas (*British Medical Journal*, March 16, 1901, p. 633) made a study of eleven cases of undoubted malignant disease of the stomach, the diagnosis being confirmed in all, either by the course of the illness and the localization of the tumor, or by the results of surgical intervention or post-mortem examination. Digestion leucocytosis was found absent in six, present in four, and inconstant in one. These results correspond closely with those related by Osler and Macrae in a monograph on "Cancer of the Stomach" published last year.

It thus appears that there is no constancy in the number of leucocytes after the taking of food in cases of gastric carcinoma, and that the absence or presence of digestion leucocytosis cannot be implicitly relied upon in the diagnosis. There is reason to believe that such leucocytosis, when it occurs, is dependent upon the activity of the digestive and absorptive powers of the stomach, and that it will fail to appear when the latter are impaired from any cause. Its absence, therefore, cannot be looked upon as an indication specifically of malignant disease, but of a state of the gastric functions that may or may not be associated with such disease. The danger of relying upon it solely or largely resides in the fact that the opportunity for successful operative intervention may thereby be permitted to escape. The clinician, therefore, must, here as elsewhere, weigh judicially all of the evidence in the case, neither ignoring nor placing too much stress upon any, and, after careful and deliberate study, reach a conclusion and act promptly in accordance therewith.

THE ETIOLOGY OF BLACKWATER FEVER.

THE London *Practitioner* has for its March edition a particularly well-written series of articles on malaria, contributed by some of the foremost authorities on the subject. The first article on the etiology, prophylaxis, and treatment of malaria is from the pen of Dr. Patrick Manson, and is, as may be well believed, an able *résumé* of the matter. Mr. D. C. Rees discusses malaria with regard to its parasitology, and Dr. Louis Sambon, the well-known Italian scientist, who lectures on tropical diseases at the London School of Tropical Medicine, treats of intermittent fevers. So much has been written upon malaria within recent years, that all that is stated concerning it is a matter of common knowledge among the medical profession, and, although the articles in the *Practitioner* present, if not the best, perhaps as good a condensed review of the malady as has thus far appeared, it will be hardly worth while here to do more than to commend the excellence of the contributions. Dr. Sambon, however, writes instructively of "blackwater fever," and as for some considerable time there has been a wide difference of opinion as to its cause among those best qualified by experience to speak with authority upon the question, it may be apposite to quote his views. These are as follows:

"The quinine theory of blackwater fever arose in Greece. It was first suggested by Veretas in 1858, and soon became popular among Greek physicians. In 1874 it was introduced into Italy by Tomaselli, and quite recently it received the support of Koch, who, even more emphatically than his predecessors, stated that 'blackwater fever was nothing more nor less than quinine poisoning.' The British physicians who have had much experience with this disease in intertropical Africa are unanimous in protesting against this theory. The idea that quinine, the great specific remedy for

malaria, could produce blackwater fever originated from a misinterpretation of the fact that its administration, even in small doses, may excite a paroxysm of blackwater fever in a patient who, having previously contracted the disease, still bears it in latent form. As quinine, even when given in highly toxic doses, never produces blackwater fever in healthy people or in malarial patients, its peculiar action had to be explained by a peculiar hypothetical idiosyncrasy. Studying very carefully the literature of the so-called 'quinine hæmoglobinuria,' I have been able to deduce the following facts:

"In regions in which blackwater fever is endemic a patient may have suffered repeated attacks of tertian or semi-tertian, which were satisfactorily treated with quinine. One day, instead of an ordinary malarial paroxysm, blackwater fever manifests itself; and the continued administration of quinine seems in some cases to aggravate the disease, in others it appears to have a decidedly beneficial influence. The first attack of blackwater fever being well over, the administration of quinine may or may not be followed by a relapse, or the relapse may occur without the administration of quinine. Later, the hæmoglobinuric infection being seemingly spent, the administration of quinine, even in large doses, never causes it again, as it previously appeared to do. Thus we see that the connection of quinine to blackwater fever is not one of cause and effect, but merely one of coincidence.

"Blackwater fever was known long before the introduction of cinchona bark into Europe. Before the days of Hippocrates a number of cases have been reported in Europeans who had not taken quinine. Cardamatis mentions thirty-two such cases. In the numerous cases in which blackwater fever has been attributed to quinine, the interval between the last dose of quinine and the onset of the disease varied from four days to two hours, and there never was any relation between the amount of the dose and the interval or intensity or duration of the attack. A number of physicians have vaunted the use of quinine in large doses in the treatment of blackwater fever. Finally, why should quinine always cure hæmoglobinuria in the endemic regions of blackwater fever and never in the multitudinous patients suffering from intermittent fevers in regions free from blackwater fever?

"In 1890 Manson stated that he believed blackwater fever to be a disease *sui generis*. In 1898 I again endeavored to prove that blackwater fever is a specific disease, basing my theory on the characteristic phenomena of the disease, on its peculiar geographical distribution, and on the striking analogy which it has to the hæmoglobinuric fever of cattle, in which Smith and Kilborne discovered a protozoal parasite, the Piroplasma bigeminum. A hæmoglobinuric fever is also found in sheep, with an exceedingly minute parasite, and goats, horses, and mules likewise suffer from a similar disease. The symptoms, the post-mortem findings, and the epidemiological features of these fevers are exactly like those of the hæmoglobinuric fever of man. It is, therefore, reasonable to infer that blackwater fever may be due to a protozoal organism akin to that of cattle, in 'red-water fever.'"

The foregoing is a strong defence of the theory that the disease in question is specific, and a severe indictment of the quinine theory as a cause. The great element of strength in the views of those who take the latter position is the fact that physicians who have practised in districts where blackwater fever is frequent, almost without exception hold the opinion that the malady is specific.

THE INSANE IN NEW JERSEY.

The past ten years have wrought notable improvements in the care of the insane in New Jersey. The State has now under public and private care approximately five thousand insane, about two thousand of whom are under State care at Morris Plains and Trenton, the remainder being in county and private institutions.

While a comparatively recent law places the county institutions under a certain degree of State supervision, we fear that such supervision has been and is now entirely inadequate effectively to safeguard the best interests of the insane. Many county almshouses still exist, in which numbers of the insane are cared for, and it is not likely that a comprehensive and effective system of State care can be brought about until there has been created in the State enough popular and well-directed sentiment to make political patronage of no importance when compared to the true interests of the State lunacy wards themselves. Cannot an associated system of charities, official or unofficial—and we think the latter better in this instance—be organized in New Jersey, to draw public attention to this need and to stimulate efforts for its accomplishment?

We are pleased to note that the State hospital at Morris Plains is taking each year a more advanced place among the best hospitals of the country. It now has a population of fourteen hundred, and has a detached building, just completed, that will provide for eight hundred additional chronic cases.

The new building is very well planned and constructed; but in view of the rapid advance in the science of mental medicine, therapy, and pathology in recent years, we cannot bring ourselves to believe that the State followed the best course in constructing so good a building, equipping it so largely with modern appliances and conveniences, including a well-planned and admirable laboratory for scientific work, when it might have followed the far better alternate course of building a strictly modern hospital nearer the centre of population, and exclusively for the acutely insane, the curable cases. We thoroughly believe that in due time the better and attractive policy of caring for the chronic insane in small homes in the agricultural districts, and of caring for the acutely insane in metropolitan districts, will be generally recognized and followed, and it seems now to us that New Jersey failed in foresight in not following this plan when it constructed the second formidable granite structure for the chronic insane at Morris Plains.

During the past eight years, Dr. B. D. Evans, medical director at Morris Plains, and Dr. Eliot Gorton,

his first assistant, have given effective attention to organizing and conducting an excellent training-school for nurses, a better system of case records, and have devoted much attention to increasing outdoor exercises and labor for patients, to building up a valuable reference library, and to an improved condition in the general medical service of the hospital.

The report of the medical director for 1900 is made to include two dozen or more statistical tables, inserted as an appendix. To remove such statistical matter from the body of the report is unquestionably a step in the right direction, but to omit it altogether would be better still, and we fail to conceive why so many progressive hospitals throughout the country continue to print these long and dry-as-dust tables, unless it is merely to follow an established and antiquated custom.

The pathological work of the hospital is done by Dr. Thomas P. Prout, who, to judge by his reports, seems to proceed with caution in all his studies and to draw his conclusions and deductions most carefully, facts which in themselves greatly enhance the value of his work.

Under the management of Mr. M. K. Everett, warden, extensive additions and improvements have been made in the water-supply and sewage-disposal systems; in the large farming interests of the hospital; and in the constructional supervision of buildings.

On the whole, the State of New Jersey is to be congratulated on the excellence of the hospital plant at Morris Plains, and its management.

ANTITYPHOID INOCULATION.

Although the subject is being industriously investigated, it cannot be said that a final opinion has been reached as to the utility of protective inoculation in the prevention of typhoid fever. Statistics of a favorable character have in the past been published, and the most recent announcement in this connection points in the same direction. Prof. A. E. Wright (*Lancet*, February 9, 1901, p. 399), of the Army Medical School at Netley, makes, through the kindness of Lieutenant-General Sir George Luck, the statement based upon official compilation that of 539 officers, men, and women connected with the Fifteenth Hussars at Meerut, India, 360 received protective inoculation in England against typhoid fever and 179 did not. Of the former 2 (0.55 per cent.) were admitted to the hospital, suffering from typhoid fever, with 1 death (0.27 per cent.); while of the latter 11 (6.14 per cent.) were attacked by the fever, with 6 deaths (3.35 per cent.). As is well known, figures cannot under all conditions be implicitly relied upon, but in the present instance there seems to be no good reason to deny their validity or dispute the inferences that they irresistibly compel; so that the conclusion seems amply warranted that the reduction in incidence of, and mortality from, the disease in the inoculated, was, in some degree at least, due to the measures employed.

Sodium Cinnamate or "hetol" is reputed to cause cicatrization around tuberculous foci.

News of the Week.

University of Havana. — Dr. Aristides Agramonte (formerly chief of the bacteriological laboratory) has been appointed to the chair of bacteriology and experimental pathology in the medical faculty of the University of Havana, Cuba.

Dr. Simon Marx writes: "Will you kindly note in your next issue a mistake on my part in the wording of the line '. . . a case in which constitutional symptoms did *not* arise, etc.' The word *not* should have been omitted. Leaving out this little word will put an entirely different construction to the sentence and would then convey exactly what I mean."

Retirement of Colonel Woodhull.—Colonel Woodhull, of the United States army medical department, has just been retired on account of age. Colonel Woodhull was graduated from Princeton in 1856 and from the medical school of the University of Pennsylvania in 1859. He entered the army in 1861 and became colonel in 1900. He acted as surgeon-in-chief in the Philippines, whence he recently returned. He served through the Civil War, and is a well-known writer on medical subjects.

The Revised Charter of the City of New York. —The charter revision bill, which has passed the legislature, and which will undoubtedly become law without vital alterations, contains the following provisions affecting the public health of the city:

Water Supply. The commissioner of water supply is to be known as the commissioner of water supply, gas, and electricity, and in addition to the duties performed by the present commissioner he must look after all the city's lighting and steam contracts, and will have control over the opening of streets for gas mains or electrical subways. The city is authorized to acquire water rights in any other State for its own supply.

Street Cleaning. The commissioner of street cleaning is directed to confine his operations exclusively to Manhattan, the Bronx, and Brooklyn, his duties in the other two boroughs devolving upon the borough presidents.

Care of the Parks. Under the present charter the park department consists virtually of three single-headed commissioners, each commissioner having practically absolute control over the parks in the borough or boroughs which he represents.

Public Charities and the Hospitals. The board of public charities is abolished and a single commissioner is substituted. He is empowered to appoint a first and second deputy. On February 1, 1902, his jurisdiction over Bellevue, Harlem, Fordham, and Gouverneur Hospitals ceases, and the management and control of them pass into the hands of a board of trustees consisting of seven members with the commissioner ex officio.

The mayor is limited in his appointment of members to lists submitted to him by the United Hebrew Charities, the Particular Council of New York of the

Society of St. Vincent de Paul, and the New York Association for the Improvement of the Condition of the Poor. The list must contain the names of not less than twice the number of persons to be appointed. The members of the board cannot be removed unless for cause and after a hearing. The term of office is seven years.

The Health Board. The revision bill provides that after January 1st next, the health board shall consist of the commissioner of health, the police commissioner, and the health officer of the port. The commissioner of health is to be the executive officer, and the department will be practically under his sole control. His salary is fixed at $7,500 a year.

The Tenement-House Commission. The salary of the new tenement-house commissioner is also $7,500, and he has the power to appoint and remove at his discretion a first and second deputy at $4,000 a year each. The duties of this department generally are to enforce all laws concerning the building, inspection, and regulation of tenements. In it will be a new building bureau for the scrutiny of plans and specifications, an inspection bureau, and a bureau of records. Hereafter, the sanitary inspection squad will be under the jurisdiction of the new department.

The Nurses' Associated Alumni of the United States filed articles of incorporation with the secretary of State at Albany on April 18th. It proposes to advance the professional and educational interests of its members. The principal office is in New York City. The directors are: Mrs. Isabel Hampton Robb, of Cleveland; Emma C. Hackett, of Chicago; Emma J. Keating, of Buffalo; T. E. Healy, of Brooklyn; Mary E. Thornton, of New York City.

The Prevalence of Smallpox in New York City.—The New York *Evening Post*, April 20th, gives statistics with regard to the incidence of and mortality from smallpox in New York City from the time that the health department commenced to keep records. The following shows the number of deaths since the year 1868, in years when they numbered more than one hundred: Year 1869, deaths 203; 1870, 293; 1871, 805; 1872, 929; 1873, 117; 1874, 484; 1875, 1,280; 1876, 315; 1881, 451; 1882, 259; 1893, 102; 1894, 154; 1901, 114. From the above it will be seen that during the past thirty-three years deaths have been more than one hundred in each of thirteen years. The percentage of mortality has been in a constantly decreasing ratio. The number of cases reported since November 1, 1900, and up to April 13th, is 599, while the number of 1874 and 1875 together was 4,648. The decrease in the percentage mortality is obviously due to more general and more efficient vaccination. Insufficient vaccination, in 1875 as in 1901, is held responsible for the spread of the disease. Hospital accommodation is still very inadequate in New York City. The statement is made, on the authority of the president of the board of health, that the department has had to crowd 225 patients into quarters intended to hold only 75. So impressed was the municipal assembly with the need of putting an end to such a state of things at once, that it has just voted an appropriation of $10,000 to be expended for new hospital sheds without the usual delay in advertising for bids. In a city of the wealth and size of New York no money or effort should be spared to guard its inhabitants against contagious diseases.

The American Association for the Advancement of Physical Education.—The twelfth annual meeting of this association was held in this city on Thursday, Friday, and Saturday of last week. The sessions were held in the hall of the Board of Education, under the presidency of Dr. Dudley Allen Sargent, of Harvard. The title of his presidential address was "Ideals of Physical Training." He said that physical training is established in the United States in some form in 270 colleges and universities, in 300 cities in their public schools, and in about 500 Y. M. C. A. gymnasiums. The North American Turnerbund has 300 gymnasiums, 200 instructors, and 15,000 members. There are perhaps 100 athletic club gymnasiums of one description or another, and a few out-of-door and public city gymnasiums. Then there are gymnasiums in private houses, churches, hospitals, sanitariums, army and navy depots, police quarters, engine-house stations, mission houses, industrial schools, and many other institutions to the number of several hundred. In addition to this form of physical training there is a great variety of special athletic clubs for boxing, fencing, bowling, boating, canoeing, swimming, and bicycling. Then there are golf, tennis, baseball, football, each with their ardent devotees. Bicycling, lawn tennis, and golf, he said, have been especially valuable to women, inducing many to exercise who never exercised before, and they have probably done more to overcome the evils of tight clothing than a whole century of preaching and lecturing on this subject. Mr. J. M. Rice, editor of *The Forum*, read a paper in which he said that much time was wasted in teaching the "three Rs," and asserted that the elimination of waste in these studies would give the schools an opportunity of doing in other lines more than twice as much as they are doing to-day. The following papers were also read and discussed: "The Place and Value of the Physical Examination on Entering College," Dr. S. Tait Mackenzie; "The Need of Physical Training in Our Public Schools," Dr. Frederick J. Simpson, Hartford, Conn.; "Glossary," Dr. J. H. McCurdy, Y. M. C. A. Training-School, Springfield, Mass.; "Effect of Athletics on Growing Boys," Dr. Watson L. Savage, Columbia University; "Value of Athletics to College Girls," Miss Harriet I. Ballentine, Vassar College; "The Function of Physical Training in High Schools," Dr. C. Ward Crampton, Boys' High School, New York City; "Some Results upon the Study of Hygienic School Desks and Chairs," Dr. Edward R. Shaw, dean of the School of Pedagogy, New York University; "The Importance of Hygienic Seats and Desks for School Children," Dr. Eliza M. Mosher, dean of the woman's department, University of Michigan; "Children's Games in the Andover Public Schools," George E. Johnson, superintendent of schools, Andover, Mass.; "The Hygiene of Instruc-

tion," Dr. Stuart H. Rowe, supervising principal, Lovell district, New Haven, Conn. On Saturday, after the close of the meeting, a complimentary reception was given to Dr. Edward Hitchcock, director of physical education at Amherst College for forty years, during which time he has served as the acting president of the institution. A dozen colleges were represented at the banquet which followed the reception. Dr. Luther Gulick, of Pratt Institute, Brooklyn, was toastmaster. Dr. R. Tait Mackenzie, of McGill University, Montreal, offered a resolution extending to Dr. Hitchcock the congratulations of the association upon the completion of forty years of continued service to physical training, and expressing the conviction that he had been an important factor in advancing this branch of education. The resolution was seconded by Dr. H. Arnold, of New Haven, and unanimously carried amid applause.

Professor Kohlstock, a German scientist, who was engaged in sanitary researches in Tien-Tsin, died in that city on April 15th, as a result of infection contracted while prosecuting his investigations.

A Municipal Inebriates' Home.—A bill has been passed by the legislature of this State, providing for the establishment of an inebriates' home in this city, and appropriating five per cent. of the excise revenue for its maintenance. The trustees named in the bill are: Drs. William T. Jenkins, A. Campbell White, John S. Richardson, Delancey Carter, Isaac N. Love, and Frank J. Cuthbertson. The City Club has asked Governor Odell to give its committee time to consider the bill before taking final action. The committee thinks it a scheme to take care of certain politicians, and wants to know the real necessity for such a home. The bill gives the trustees power to take persons from prisons—a provision which seems to place the home's controlling board higher in authority than the magistrate. Another objectionable feature is that the board of trustees is self-perpetuating, filling vacancies itself.

Trouble in the Pathological Institute.—The State Lunacy Commission has notified Dr. Ira Van Gieson, director of the Pathological Institute of the New York State Hospitals for the Insane, that his services will not be desired after May 1st. This is the outcome of a dispute that has long been going on in regard to the Pathological Institute, its opponents on the commission asserting that, although it may have done work or research of great value to the scientific world, it has done little work of value to the State hospitals. This is denied by the members of the working staff of the Institute, who hold that the work they have done has been of great utility to the State hospitals. It is possible that the entire staff will resign if the commissioners persist in their intention of forcing out the director.

Christian Scientists in Germany.—The press of Berlin is devoting attention to the efforts of the Christian Scientists in the American colony, who are now holding two services every Sunday, one in English and one in German, at the residence of an American. The *Kreuz-Zeitung*, a Catholic paper, asserts that the leaders of the movement are projecting several churches, including one in Berlin, and it characterizes the movement, with some bitterness, as "an inroad of Anglo-Saxon Protestantism." The leading Evangelical weekly is also opposing the movement as one of evil promise for Germany.

Dr. Edward N. Liell, of Jacksonville, Fla., has been selected to deliver the anniversary address at the next meeting of the Florida Medical Association, to be held in Tampa in April, 1902.

Yellow Fever on a British Warship.—The *Condor*, a British war-vessel, has arrived at Victoria, B. C., from Acapulco, Mexico, with yellow fever among its crew, and has been quarantined.

Quarantine Commissioners.—Governor Odell has reappointed Hugh McRobert and Frederick H. Schroeder as New York quarantine commissioners, and appointed Charles H. Murray to succeed Edmund J. Palmer in a similar capacity.

A Dinner to Dr. L. L. Seaman was given by his friends at the Lotos Club last Saturday. Dr. Seaman has just returned from an absence of six months in China and the Philippines, and the dinner was given in order to welcome him back to this city.

The Sick in Manila.—Colonel Woodhull, chief surgeon in Manila, reports to the War Department that on April 16th there were 3,933 men sick in hospital, making a sick percentage of 7.39 per cent., which is slightly above that reported April 1st, which was 6.89 per cent.

Tuberculosis and School Attendance.—Colorado State Health Commissioner Clough has promulgated a rule excluding from the public schools all teachers and children who are suffering from tuberculosis. When the disease is known to be in a family the child must present a certificate from the family physician, declaring there is no danger of contagion.

The State Hospital for Consumptives.—The committee on rules of the assembly has amended Senator Davis' bill for the construction of a State Hospital for Consumptives in the Adirondacks, so as to provide that the commission to review the selection of the site shall consist of the governor, the speaker *pro tem.* of the senate, and Speaker Nixon of the assembly. Governor Odell has appointed Norman S. Dyke, of Brooklyn, a member of the board of trustees of the hospital, in place of Walter Jennings.

The Rinderpest in the Philippines.—A Manila despatch to *The Sun* states that the rinderpest is spreading in the provinces of Tayabas and Pangasinan and in several more remote districts in Luzon. The board of health is making a strong fight against the spread of the disease among the animals, and has sent military doctors to investigate the conditions in the localities where the disease prevails.

Tennessee State Medical Society.—At the sixty-eighth annual meeting of the Tennessee State Medical Society the following officers were elected: Deering J. Roberts, M.D., Nashville, *President;* J. B. Murfree,

Jr., M.D., Murfreesboro, L. A. Yarbrough, M.D., Covington, W. B. St. John, M.D., Bristol, *Vice-Presidents;* A. B. Cooke, M.D., Nashville, *Secretary;* W. C. Bilbro, M.D., Murfreesboro, *Treasurer.* The next place of meeting will be Memphis, Tenn., on the second Tuesday in April, 1902.

The St. Paul Meeting and Yellowstone Park.—Arrangements have been completed for an excursion of the members of the American Medical Association to Yellowstone Park. A special train will be run from St. Paul to the Yellowstone Park, and the rates will be very low, but how low cannot at this time be definitely stated.

Dental Department of the University of Michigan.—It is announced that in the fall of 1901 the dental department of the University of Michigan will institute a four-years' course of study, with increased requirements for admission.

To Investigate Florida Cattle Disease.—The United States Bureau of Animal Industry has authorized Victor A. Norgard to proceed to Florida to study the cattle disease known as the salt sickness. This course has been taken at the request of the State Convention of Stockmen, which at its meeting discussed the matter, and declared that the disease was one of the greatest drawbacks to the Florida stock business.

Lunatics in the French Army and Navy.—A French writer is responsibility for the statement that of every 100,000 men of the army or naval professions 199 become helpless lunatics. Among mechanics the number is only 66 per 100,000.

Pathological Society of Philadelphia.—At a stated meeting held April 11th, Dr. H. F. Harris presented a communication entitled "Experimental Dysentery in Dogs." By means of rectal injections of discharges from dysenteric patients it was possible to excite in puppies a condition attended with the symptoms and the lesions of dysentery, and with the presence of amœbæ coli in the stools and in the tissues. In several instances abscess of the liver also was found as a complication. Dr. Harris read further a communication entitled "A New Method of Staining Elastic Tissues with Hæmatein." Drs. W. E. Robertson and D. J. McCarthy presented "A Brain Weighing Fifty-two Ounces from a Child Six Years of Age." Death had resulted from typhoid fever. The mental state during life presented no noteworthy peculiarity. In addition to its enlarged size, the brain exhibited also several anomalies in fissuration. Dr. Randle C. Rosenberger read a paper entitled "Bacteriological Examination of Clinical Thermometers." As a result of an investigation upon this point, he had found that bacteria could often be demonstrated on these instruments when employed in the ordinary way, and even when kept in receptacles containing a small amount of formalin or carbolic acid. Dr. George B. Wood exhibited a specimen of "Endothelioma of the Cheek," concerning whose exact histological nature there was some doubt. According to other opinions, it was thought to be a rodent ulcer, or an angiosarcoma, or a perithelioma. Dr. W. M. L. Coplin, for Dr. W. D. Eaton, exhibited a specimen of "Strongylus micrurus Found in the Lung," and described "A New Permanent Stain for Lardacein." Dr. W. E. Robertson exhibited a specimen of "Cyclopean Monster." An interesting fact was that the mother had been operated on for carcinoma of the cervix uteri in the twelfth week of pregnancy. Dr. Joseph Walsh exhibited a specimen of "Tumor of the Brain Involving the Frontal Lobe."

School Closed on Account of Diphtheria.—The closing of the public school on Ogden Avenue, in the Bronx, on Thursday, April 18th, has aroused attention to the prevalence of and mortality from diphtheria and scarlet fever in the Bronx. The records in the Bronx, from January 1st to April 13th, show deaths from diseases as follows: Diphtheria, 357; scarlet fever, 357; measles, 83; tuberculosis, 209; croup, 39; chickenpox, 10; smallpox, 115. The prevalence of these diseases has been attributed to scarcity of water.

A Fat Bill.—It is reported in the daily papers that the estate of the late Senator "Chris" Magee has received a bill from Dr. Walter C. Browning, of Philadelphia, for $190,000 for professional services. Dr. Browning was in attendance on Senator Magee for twenty-one months previous and accompanied him to several places in the effort to recover his health. The charge is at the rate of $80 per hour for visits and actual attendance. One item is $17,000 for last summer's treatment at Atlantic City, and another for $12,000 for accompanying the senator to Hot Springs, Virginia.

Smallpox on Transport "Lawson."—The transport *Lawson* left Manila on March 16th, and two days later First Lieutenant Harry E. Courtney, of the Thirty-ninth Infantry, was taken down with smallpox. He was sent to the United States hospital at Nagasaki on the transport's arrival there. After being fumigated, the *Lawson* started for San Francisco, but on March 31st two more cases of the disease appeared; Lieutenant Courtney's roommate, Lieutenant Charles H. Cobb, Jr., of the Thirty-ninth Infantry, and Assistant Surgeon H. H. Stromberger being attacked with the disease. As the transport was running short of coal, she was headed for Honolulu and the patients were landed there.—*New York Tribune.*

The Negro Problem Discussed at Washington.—The negro problem was discussed at Friday's (April 19th) session of the American Social Science Association. Professor Kelly Miller spoke in favor of the higher education of the negro. He contended that it was fallacious to assert that viciousness increases with education, and said that negro graduates of universities and colleges are law-abiding, and exercise a wholesome influence on the masses. He was of the opinion that the only effective method to make them better citizens is to equip them with more advanced ideas through education. George K. Stetson drew attention to the fact that racial antagonism is a natural instinct and a universal law. The antagonism between the mulatto and negro, he affirmed, was much greater than that between the white and the negro. The negro, he thought, should be the means of elevat-

ing the race. Dr. W. T. Harris, commissioner of education, pointed out the wonderful strides in negro education, and paid a eulogistic tribute to Booker F. Washington. F. B. Sanborn, of Massachusetts, also spoke. Dr. Anderson made a fierce attack on the negro race, from the standpoint of inferiority to the white race, to which several colored professors replied.

Philadelphia Pediatric Society.—At a stated meeting held April 9th, Dr. L. Emmett Holt, of New York, delivered an address, entitled "Some Forms of Indigestion in Infants and Young Children, with Especial Reference to their Dietetic Treatment." He pointed out that while a healthy child will often be able to eat with impunity milk mixtures and even milk substitutes of most diverse composition, the greatest and at times even insuperable difficulty may be encountered in the feeding of a sick child. The difficulty can often be traced to dietetic errors committed in the first weeks or days of life. That a given diet is appropriate for the individual child will be indicated by its steady increase in weight and by its freedom from pain, and long hours of sleep. Much good can often be effected by doing less rather than more. Thus constipation need not always be attacked, unless other symptoms are present; nor irrigation of the bowel practised frequently and for long periods, because of slight increase in the frequency of the stools and the presence of mucus. Sometimes, further, milk will be better borne for being given in greater rather than in progressively decreasing concentration. Breast-milk may at times be distinctly harmful. More often, of course, when the mother is unable to nurse her infant, and feeding disagrees, a wetnurse is the best solution of a difficult problem. Each case must be studied for itself and receive the individual treatment its condition demands.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending April 20, 1901. Passed Assistant Surgeon N. J. Blackwood detached from the naval hospital, Philadelphia, April 17th, and ordered to the *Alliance*. Passed Assistant Surgeon L. Morris detached from the naval academy and ordered to the naval hospital, Philadelphia, April 17th. Assistant Surgeon R. E. Peck ordered to the *Pensacola*, April 25th. Surgeon J. F. Urie detached from the *Dolphin*, April 20th, and ordered to the marine recruiting rendezvous, Boston. Surgeon E. P. Stone detached from the naval dispensary, Washington, D. C., April 19th, and ordered to the *Dolphin*. Surgeon F. Anderson ordered to the naval dispensary, Washington, D. C., April 19th. Surgeon J. E. Gardner detached from the marine recruiting rendezvous, Boston, and ordered to the naval hospital, Cavité, P. I., April 22d. Assistant Surgeon C. G. Smith appointed assistant surgeon April 12, 1901. Surgeon W. F. Arnold detached from the *New Orleans* and to duty at Olengapo, P. I. Passed Assistant Surgeon A. Alfred ordered to duty with the marine brigade, Cavité, P. I. Assistant Surgeon E. J. Grow detached from the *Glacier* and ordered to the *Isla de Luzon*. Assistant Surgeon J. Stepp detached from duty with the First Regular Marines, Cavité P. I., and ordered to the *Castine*. Assistant Surgeon H. C. Curl detached from the *Castine* and ordered to Cavité, P. I.

Obituary Notes.—Dr. George W. Cox died at Philadelphia, on April 19th, at the age of sixty-one years. He was graduated from the Medico-Chirurgical College in 1878.

Dr. Lewis R. Kirk died at Rising Sun, Md., on April 19th, at the age of sixty-nine years. He was a graduate of Jefferson Medical College.

Dr. H. Scruggs, of Memphis, Tenn., was shot and killed on April 17th, it is thought, by a political opponent, whom he defeated in an election contest last autumn. Dr. Scruggs was a graduate of the Memphis Hospital Medical College in the class of 1885.

Dr. Frederick J. Brockway, of this city, died of meningitis at Brattleborough, Vt., on April 21st. Dr. Brockway was born in South Sutton, N. H., February 24, 1860. He received the degree of Bachelor of Arts from Yale and his medical degree from the College of Physicians and Surgeons in 1887. He was an assistant demonstrator of anatomy in that institution, and was also a member of the County Medical Society, the New York Academy of Medicine, the New York Academy of Sciences, the Alumni Association of Roosevelt Hospital, and the West End Medical Society.

Dr. Almon V. Belding, ninety-four years of age, died on Friday night, April 19th, at the house of his daughter, Mrs. Angle, in Averill Avenue, Rochester. He was born in Phelps, N. Y., and came to Rochester in 1867.

Progress of Medical Science.

Philadelphia Medical Journal, April 20, 1901.

The Localization of Brain Tumors, Especially with Reference to the Parietal and Prefrontal Regions.—Charles K. Mills concludes that the diagnosis of the existence of a brain tumor can sometimes be made even in the absence of most of the general symptoms, such as optic neuritis, headache, vertigo, and vomiting, chiefly by the close study of localizing and invasion symptoms. Emotional states, even hysterical stigmata, are sometimes present in cases of brain tumor, and must not be given too much weight in differential diagnosis. Tumors of the posteroparietal region, and especially of the superior parietal lobule (parietal of Wilder), give as their most important localizing symptoms disorders of cutaneous and muscular sensibility, and especially astereognosis; other symptoms often present in such cases are the result of compression or invasion of adjoining regions. Tumors and other lesions implicating the angular gyre and the regions adjoining (the subparietal, first temporal, and medio-occipital convolutions) give as their main localizing symptoms word deafness and word blindness, with the usually accompanying speech disturbances, lateral homonymous hemianopsias, and disorders of cutaneous and muscular sensibility, including astereognosis. Just as the centres for hearing, vision, and speech are more highly differentiated in the left hemisphere, so it is probable that the stereognostic sense is more highly evolved in this hemisphere. A tumor strictly confined to the motor regions does not give objective sensory phenomena of a persisting character; the localizing symptoms of a growth so situated are motor, chiefly paralysis and monospasm, with also exaggerated deep and superficial reflexes. In tumors of the motor subcortex tonic spasticity is usually a marked symptom. Paresis or paralysis, and exaggerated reflexes, with monospasm or unilateral convulsions, may also be present. Tumors of the prefrontal region, by which is meant the region entirely cephalad of the motor zone, chiefly give psychical symptoms of an especial char-

acter; when the tumor is situated on the left side, motor agraphia (or orthographia) and motor aphasia are usually present because of the compression or invasion of the posterior portions of the second frontal and of the third frontal convolutions; paralysis and other motor symptoms are often present late because of encroachments upon the motor region.

Susceptibility to Disease and Physical Development in College Women.—Arthur MacDonald gives certain tentative conclusions from the study of fourteen hundred and eighty-six students. Those who report no diseases are less in weight but greater in height and lung capacity, and about equal in strength to those having had one or more diseases. The difference between those having had one or more diseases and those with constitutional disease is that the latter are shorter in stature than the former, but in strength, weight, and lung capacity there is no marked difference. The typhoid cases compared with all cases of specific infectious diseases are inferior in weight, height, and strength. This would seem to bear out partly at least Hildebrand's idea, that delicate, slender people are far more subject to typhoid fever than to consumption. The cases of infectious diseases are superior in weight, lung capacity, height, and strength to those having diseases in general. Those having hereditary diseases are inferior in weight and slightly so in height to those having had diseases in general. Diseases of the digestive system show cases of less weight and lung capacity but of greater height than diseases in general. Those with insufficient respiration have less weight but greater lung capacity and height than those with disease in general. Cases of heart murmurs show greater weight, lung capacity, height, and strength than cases of disease in general. Those with habitual headache are inferior in weight, height, lung capacity, and strength to those with diseases in general.

Boston Medical and Surgical Journal, April 18, 1901.

Leucocytosis and Typhoidal Perforation.—Colin K. Russell concludes from the study of several cases: (1) That in perforation it is the general rule to have a leucocytosis, but that the degree may vary within wide limits. (2) That the leucocytes, while appearing as a rule early, may not be at all marked until the general peritonitis and collapse have supervened. (3) That there may be an utter absence of leucocytosis with marked perforation and peritonitis; in fact, that the count may be lower than normal. (4) That with typical signs of perforation and a definite leucocytosis there may be no such complication present, and an operation may be performed unnecessarily. (5) That a marked degree of leucocytosis may occur in complications other than perforation, for example, bronchitis, cholecystitis, etc. (6) That with pain and tenderness in the abdomen, coming on suddenly during an attack of typhoid fever (and in the absence of evidences of cholecystitis or other definite complication) and a distinct leucocytosis, even without other signs of perforation, an exploratory operation is justified, even advisable, thereby obviating the dangers of a fatal issue from too great a delay.

Contusion of the Abdomen; No External Wound; Rupture of the Descending Colon; Fecal Abscess; Drainage; Suture of Ruptured Gut; Recovery.—Charles L. Scudder reports a case, the particular interest of which lies in the fact that the rupture of the bowel was not attended by such symptoms as would ordinarily lead one to suppose that a serious injury had been received. The symptom of severe and continuous vomiting was misinterpreted, and should have suggested a lesion of the bowel, or at least serious involvement of the peritoneum.

Upon what Sort of Information Shall a Medical Examiner Hold a View?—By H. M. Culls.

The Opinion Evidence of Medical Experts.—By John D. McLaughlin.

The Umillian Murder.—By Herbert B. Perry.

New York Medical Journal, April 20, 1901.

A Case of Cystinuria Ending in Recovery.—John Reid reports the case of a German cook aged thirty-two years who complained of great pain in micturition, especially toward the end of the penis; and on examination a small ulcer was found in the urethra on the left side and about an eighth of an inch from the meatus urinarius. It was covered with thick pus and appeared to be progressing toward resolution, while it was so tender to the touch as to make one suspect imaginative fear. The urine had a sweetbrier odor, was of about normal color, and was without albumin and sugar, but on being boiled with liquor potassæ yielded ammonia. A portion evaporated on a slide showed hexagonal laminæ under the microscope, soluble in ammonia water and in liquor potassæ, and reprecipitated by acetic acid in crystals which dissolved in hydrochloric acid. The ammoniacal solution, evaporated, gave the six-sided crystals. On incineration, the characteristic odor of garlic was produced. A diagnosis was made of cystinuria, and on the theory that the disease is due to arrested metabolism a mixture was ordered containing quinine, salicylic acid, and rhubarb—only temporary relief was obtained. For the urethral ulcer calomel was used locally with success. Internally iron and strychnine were employed, and the patient was finally cured. The author says that there are on record only about eighty cases of this disease since it was first recognized by Wollaston some ninety years ago. The disease is said to be due to some fermenting organism. Cystin can be artificially formed by acting on fibrin with calf's pancreas and salicylic acid for a long time. Text-books report that cases go on for years without symptoms, but to the author's knowledge no cure has hitherto been reported.

Acute Spinal Ataxia (Non-Tabetic) and its Relation to Other Forms of Acute Ataxia.—C. L. Dana says that acute ataxia occurs occasionally in tabes dorsalis, but is associated usually with characteristic symptoms. Acute non-tabetic spinal ataxia occurs as a manifestation of spinal syphilis or senile arterial changes, and shows itself by a sudden onset of temporary motor weakness and bladder troubles, great ataxia, and minor sensory disorders. It may affect only one extremity, but usually affects the lower limbs. The tendency is to nearly complete recovery. Acute bulbar or bulbocerebellar ataxia occurs as a sequel of some acute infection, and is usually the beginning of a form of multiple sclerosis. Acute neuritic ataxia occurs as the result of multiple neuritis of the sensory type. It is seen usually in the non-alcoholic forms of neuritis, especially those due to metallic poisons, like arsenic, or to diphtheria.

Grippe, Pneumonia, and Insanity.—E. Aronson gives a report of the case of a woman, age not stated, who presented the sequence of conditions enumerated in the title. At the time of the report the patient was doing well and bade fair to recover entirely her health. The insanity was of the maniacal type with great hyperæsthesia of the abdomen.

Journal of the Amer. Medical Ass'n, April 20, 1901.

A Contribution to the Study of Mountain Fever.—R. Harvey Reed finds in the arid plateaus of the Rocky Mountains three types of febrile disturbances that predominate during the summer and fall. These are locally called malaria, typhoid, and mountain fevers. The latter is characterized chiefly by a sudden attack of malaise, followed by a chill, a sharp rise and fall of temperature, often to unusual extremes; occipital headache with pain shooting down the back, but seldom accompanied with loss of consciousness or associated with epistaxis. There is some gastro-intestinal irritation which seems to be confined more particularly to the stomach and transverse colon. There is rarely enteric hemorrhage or vomiting, and it is only occasionally associated with tympanites. Usually between the tenth and fifteenth days a peculiar eruption appears which extends over the upper extremities, the anterior and posterior portion of the chest, the abdomen, the back, the hips, the thighs, and, not infrequently, the legs. The eruption first consists in a small, bright-red spot between the size of a pin-head and a split pea, which under the finger feels like a small grain of shot in the skin, which is slightly raised at the point of discoloration and is neither vesicular nor pustular. In from three to five days it begins to fade and turn from a red to a dirty brown color. The shotty feeling gradually disappears, the discoloration slowly subsides, and in from seven to ten days more it disappears entirely, this generally marking the initiation of the convalescence, which requires from ten to twenty days longer, making the usual course of the disease range from thirty to fifty days. As to the differences between this fever and typhoid the following are the most important features: (1) In the reaction with Widal's test a large majority of cases show a positive reaction in typhoid fever, while in mountain fever the majority of tests show a negative reaction.

(2) The mortality is much greater in typhoid than in mountain fever. (3) The average duration of the disease is greater in typhoid than in mountain fever. (4) The cause of mountain fever does not seem to be due to the presence of the Eberth and Gaffky bacillus. (5) The rise and fall of temperature in mountain fever is more abrupt than that of typhoid. (6) Tympanites is nearly always present in typhoid and seldom present in mountain fever. (7) Epistaxis is common in typhoid, but rare in mountain fever. (8) Enteric hemorrhage is seldom met with in mountain fever, but common in typhoid. (9) The eruption in typhoid fever is usually confined to the abdomen, is not raised, and disappears readily on pressure, returning promptly when the pressure is relieved, while the eruption in mountain fever covers almost the entire body, is raised, and has a shotty feeling under the finger, and does not disappear on pressure.

A Study in the Hæmatology of Neurasthenia.—C. H. Lodor finds in all cases coming under his observation some hæmic disturbance, no matter whether the case has as a basis an autotoxæmia, a toxæmia as a sequel of preceding disease, or is apparently purely acquired or is of distinctly hereditary type. Each type may have some particular prominent symptom, a sexual one or gastric one, but be the type or special symptom what it may, if the disease persists any length of time there presently appears a condition of blood fairly constant and typical of the disease. The reds may or may not be reduced in count, at times may be even above count, but the individual erythrocyte has undergone a change so that it resembles the cells in normal blood, which Loder has called, for want of a better name, old cells. In many cells the cytoplasm in stained specimens seems pushed out to the periphery to such an extent that the cell becomes dumbbell-shaped instead of the normal lenticular or biscuit shape. As a result the cells pack together closely and show a marked diminution in volume by the hæmatokrit. The oxygen-carrying capacity is lowered, and in consequence the hæmoglobin is deficient in color test. The blood in neurasthenia then would seem to be poor in oxygen-carrying capacity, and not only this, but, owing to the poor vasomotor control, the peripheral blood at least varies much in its character.

The Physiological Care of Colds.—C. H. Shepard says that the invariable cause of colds comes from within, not from without. Frequent faults are highly seasoned foods and eating too often, a deficient supply of pure air, the use of narcotics, and the omission of the bath. For treatment he gives the following advice: To make a radical cure of a cold let the patient abstain entirely from food for at least twenty-four hours. Should the bowels be at all inactive, it is desirable that they be thoroughly flushed with warm water. He should drink freely of pure water, taking a brisk walk in the open air, and then a Turkish bath. This may well be followed by an oil rub, sometimes called a Roman bath, which mollifies the skin, making it more flexible and active. The patient will find a permanent benefit therefrom. The internal pressure will be relieved, and the cure perfected. Necessarily chronic cases need more persevering treatment, but each day will show progress, and only perseverance is needed to triumph ultimately over the morbid action.

Atrophy of the Mucous Membrane of the Stomach.—F. F. Ward calls attention to the fallacy of the statement so frequently made that absence of hydrochloric acid is to be regarded as proof positive of the existence of malignant disease. As to diet in the class of cases forming the basis of his discussion, he says that we must depend on farinaceous food and that the patient must be urged to eat freely thereof. In addition we must give some mild astringent which will be at the same time a disinfectant and tonic to the intestines. The author's two favorite drugs for this purpose are tannigen and tannalbin.

Some Points in the Diagnosis of Gall Stones.—J. B. Herrick says that the symptoms to be carefully analyzed in a suspected case are the pain, icterus, fever, possible association with carcinoma, the existence of Riedel's tongue-shaped process, *i.e.*, a projection of the lower anterior border of the liver, and the possible existence of an antecedent typhoid fever. Symptoms of gall stones may be stimulated by those of angina pectoris, senile pneumonia, and localized peritonitis; more rarely by those of hernia of the linea alba, Dietl's crises in floating kidney, hysteria, malaria, with jaundice and neuralgic pains.

Some Notes on Two Cases of Voluntary Laryngeal Whistling.—G. H. Makuen reports the cases. In one case it was found that the aryepiglottic folds were used as are the lips of the mouth in whistling. The other patient could imitate birds and could produce three and at times four distinct notes at once. He whistled somewhere down in the region of the larynx, but the action of the structures named in the first case could not be determined, as he could not whistle with the mouth opened, and therefore larygnoscopic examination during the whistling could not be made.

Acute Traumatic Malignancy.—William B Coley concludes his article in this number. He believes that injury constitutes a far more important factor in the causation of malignant tumors, both sarcoma and carcinoma, than has been generally recognized. He has had a series of two hundred and seventy cases of sarcoma, of which eighty-six, or 31.8 per cent., have a distinct history of antecedent trauma; while in thirty-one, or 11.5 per cent., the tumor developed almost immediately after the injury. If an etiological relationship can be established between the trauma and the development of the sarcoma in the group of acute cases, the same relationship will probably be found to exist in the cases of slower development. Instead of overestimating the percentage of cases with antecedent trauma, we probably underestimate it, since in the slow cases the patient has probably quite forgotten the injury. A very slight injury is sufficient to produce the growth. The writer believes that the relationship between antecedent trauma and the development of sarcoma or carcinoma can be most rationally explained on the theory that such tumors are infections, or of micro-parasitic origin. The most probable explanation would appear to be, that the micro-organisms exist latent in certain individuals, and under normal conditions they remain harmless indefinitely. The local trauma, however, diminishes the vitality of the tissues, and hence their resisting-power, and the germs, previously innocuous, gain a foothold and develop. From a study of his cases the writer concludes that trauma is a very important factor in the causation of malignant tumors. This relationship between injury and malignant tumors furnishes additional and by no means unimportant evidence in support of the infectious origin of such tumors. There follow the histories of thirty-one cases in support of these theories.

Epistaxis.—Charles N. Cox, in discussing the etiology and pathology of this affection, states that it may arise from some systemic condition or, what is most frequent, be due to some local morbid condition within the nasal cavities. Among the general conditions are plethora, anæmia, the hemorrhagic diathesis, and organic disease of the heart, liver, or kidneys. It occurs in certain acute diseases, as typhoid fever. But the majority of cases of nasal hemorrhage are due to some intranasal lesion. The most frequent injury which gives rise to epistaxis is a blow or fall upon the nose. The most frequent seat of hemorrhage due to local causes is the triangular cartilage of the septum, just within the vestibule. A deviation or spur of the septum, so placed that the air in breathing causes dryness and discomfort, is an indirect cause of bleeding, since the patient is forced to blow the nose hard or even to pick it to remove the crusts on the mucous membrane. An abrasion is formed, and later ulceration, and even perforation, may develop. Varicose veins of the septum may cause hemorrhage, as may also tumors. Vicarious epistaxis sometimes takes place. In treating this affection the nostrils should be well exposed by a nasal speculum. A head mirror is generally necessary. The electro-cautery is an effectual means of arresting hemorrhage. Dried extract of suprarenal capsule is one of the most powerful vasomotor stimulants. A twenty-per-cent. solution of ferropyrin in water is a very clean and excellent astringent and styptic application. If attacks of bleeding from the nose are at all frequent, it is of great importance that the cause be ascertained and the proper remedy applied.

An Historical Sketch of the Department of Medicine and Surgery of the University of Michigan.

Some Errors in the Examination of Urine.—By Louis Heitzmann.

British Medical Journal, April 13, 1901.

Case of Cavernous Angioma of the Orbit.—A. L. Whitehead reports the case of a man aged fifty-one years. His right eye was pushed forward by a rounded elastic tumor lying behind the eyeball. Ulceration of the lower part of the

cornea from exposure had already set in. The pupil was dilated, and the movements of the eyeball were almost lost. Vision was $\frac{6}{60}$, and the fundus appeared healthy, the physiological cup being very deep. The history was that of gradually increasing prominence of the right eye, first noticed about ten years previously, no pain or particular discomfort being felt until fourteen days before the patient was seen, which then probably occurred from corneal ulceration. In three days the growth was removed. It measured 5.4 cm. antero-posteriorly and 3.7 cm. in its greatest diameter. The tumor consisted of three lobes, each covered by a thin fibrous capsule, and was composed of a fine network of connective tissue enclosing small alveolar spaces lined by flat endothelial cells and containing masses of red blood corpuscles. The growth was elastic, but moderately firm. The patient made an uneventful recovery, the vision being now $\frac{6}{9}$, and there is almost complete range of movement of the eye in all directions.

A Note on Acute Dilatation of the Heart.—H. Oliphant Nicholson believes that in certain grave states of cardiac dilatation and in advanced valvular disease, the actual blood pressure may be enormously high, for the ventricle is called upon to work at its highest pressure. Although in certain cases in which there was observed the coexistence of advanced cardiac dilatation, feeble low-tension pulse, and immensely high systemic blood pressure, he did not pay special attention to the accentuation of the second aortic sound, still these signs just mentioned suggest that this sign would have been present. He does not believe an abnormally low pressure in the arteries, as is often found in acute pneumonias of children, incompatible with an accentuated aortic second sound, but thinks it is full of meaning; for what seems a high tension in the vessels at one time may really be a relatively low one, and *vice versa*, when all the existing factors are fully examined. For when a ventricle is acting at its highest limit an apparently poor tension may mean very little, since the blood pressure is relatively high for the state of the heart and the blood-vessels.

The Resistance of the Larval Mosquito to Cold.—M. J. Wright has carried on numerous experiments with mosquito larvæ which prove their resistance to cold. He placed a cup containing larvæ on the gardeu wall while there was about six inches of snow on the ground. After forty-eight hours' exposure the larvæ were still alive. Salt was mixed with ice and packed in a bowl about the cup, and the water slowly frozen. As long as there was any water left the larvæ lived, but as soon as the water became solid they died. Prolonged low temperature by intermittent freezing did not kill them till the water became solidified. It seems reasonable to suppose from these results that the larvæ provide for the continuation of the species through the winter in the northern countries, and probably throughout Europe. Pupæ do not seem to bear great cold well. It is during the winter that most can probably be accomplished toward exterminating mosquitos.

A Case of Recurrent Alcoholic Peripheral Neuritis.—Leslie H. Jones believes that he has seen many cases remarkable for the fact that the intense neuritis, which affected almost the whole muscular system, was caused by a very moderate amount of alcohol. He relates the case of a woman who was sent to him suffering from absolute paralysis of the extensors of the hands and feet. The patient, after total abstinence for four years, during which time she was treated by electricity, recovered the use of her muscles. Later she had recourse to stimulants again, when the old trouble returned, though not to so marked a degree. Again, after two years' abstinence and the use of electricity, she has again recovered. The writer believes that in the recent outbreak arsenic has acted on systems saturated with alcohol much as a candle-end or a resin lighter would on a smouldering fire.

The Saline Treatment of Dysentery; Based on Eight Hundred and Fifty-five Cases with Nine Deaths.—W. J. Buchanan gives his method of using salines: R Sodii sulphatis ʒ i.; aquæ fœniculi ad ʒ i. This was given four, six, or eight times a day (each dose representing one drachm of the saline) as the case required. No dose was repeated on the following day till the stool had been inspected. The saline was continued till every trace of blood and mucus had disappeared. In most cases the inflammatory products had disappeared completely in two or three days. This method is advocated for acute cases only.

A "Sign" of Mumps.—Fred. Tresilian states that generally the opening of Stenson's duct on the inner surface of the cheek outside the second upper molar is hard to discover in children; in many cases of mumps which he has observed it was a bright red papilla, and lasted as such for a week or more. Salivation also occurred in many cases.

The Treatment of Dysentery.—H. B. T Symons advocates in this disease douches every four hours of a solution of tannic acid ʒ ss. to a pint of warm water. Hot hip baths beforehand relieve hypogastric discomfort and local smarting. A little opium, rest in bed, and a strict milk diet should comprise a routine.

The Lancet, April 13, 1901.

Post-Partum Hemorrhage.—By E. S. Bishop. The author gives a vivid picture of this terrible accident and lays down some very definite rules for treatment. This consists of two main procedures. First, the foot of the bed should be elevated to an angle of from 45° to 50° with the floor, or we should immediately place the patient in the Trendelenburg position. Mere simple elevation of the foot of the bed is useless. By means of the manœuvre described the venous bleeding is greatly checked. Second, external compression of the aorta should be made by applying the closed fist with its ulnar surface resting upon the aorta as it lies over the left side of the vertebral column, and just sufficient pressure should be exerted obliquely backward and toward the right as to compress the vessel against the unyielding surface beneath, *i.e.*, the spine. In this way five-sixths of the blood supply to the uterus is shut off; the remaining sixth, that which comes through the ovarian arteries, is sufficient to maintain the integrity of the uterine fibres. Enough blood will be sent to the organ to preserve its vitality, assist in the formation of small plugs in the open arterial mouths, vivify and strengthen the muscular tone, which temporarily is at too low an ebb, so that when once more the full force of the blood-current is allowed to bear upon them the vessels shall be found closed by clot and constricted by the now firmly contracting fibres around. Pressure, as advised, should be kept up till the pulsation under the fist (at first very weak) is felt to be full and strong, and then the pressure should be very gradually lessened. During the existence of compression we can clean out the uterus, transfuse, sew up a split perineum, etc. The hæmostatic measures just named are useless so long as bleeding is going on. When once it is checked, they immediately demonstrate their value. Bishop claims that the rules he lays down are nothing but the application of common-sense surgical procedures to what is perhaps one of the most trying clinical emergencies falling to the lot of the practitioner.

On the Importance of Early Diagnosis and Treatment in Surgical Diseases of the Abdomen.—By W. Rose. Attention is called to the fact that many conditions formerly considered medical now come under the surgeon's care, and that prompt intervention will often save the life of a patient who under the old order of things was surely doomed. Of these conditions the author makes two classes: first, those due to inflammatory processes; these comprise perforation of a gastric ulcer, rupture of the intestine, and perforation of the vermiform appendix. Second, those due to neoplasms; the latter group comprises cancer of the stomach, cancer of the pylorus, and intestinal cancer. The various symptoms of the maladies named are passed in review and their differential features dwelt upon. Attention is also called to the fact that the symptoms of functional troubles sometimes simulate those of organic changes, and that the two overlap. In such instances it is not always possible to make a certain diagnosis. In such circumstances the patient should be told the facts; the advantages and risks of an exploratory incision should be pointed out and the decision be left to him or to some one qualified to act.

Remarks on Enlargement of the Inguinal Glands Chiefly in Connection with the Diagnosis of Primary Syphilis.—By A. Cooper. In typical cases and when the condition has reached its height, a group of glands—from three to six or more—can be felt in each groin. The patient must be in

the recumbent position to have the examination properly made. Besides being multiple, the glands are also indolent and separate; that is, they are not painful when handled and can by palpation be clearly defined and isolated from the others. They are freely movable beneath the skin, are of moderate size, and more or less hard. Both sides are generally affected, but occasionally one groin alone may be involved, and that not always on the same side as the specific lesion. Although multiple indolent glands form one of the most important features of primary syphilis, it must be remembered that they are not in themselves proof of it, and that an apparently typical condition of the groins is sometimes due to other causes, more especially in persons whose glands are unusually susceptible. Among such cases may be mentioned severe gonorrhœa, urethral irritation from too strong injections or other injury, irregular herpes, severe balano-posthitis, and tuberculosis. The diagnosis will depend on the history, on the absence of an indurated primary lesion, and on careful watching throughout the incubation period of syphilis.

Remarks on the Holmgren Test.—By F. W. Edridge-Green.

French Journals.

Influence of Certain Alimentary Principles on the Secretion of Gastric Juice and its Richness in Pepsin.—Mme. Potapon-Pracaïtis concludes that a preparatory repast sufficiently abundant and resistant to the action of the gastric secretion is indispensable to allow one to determine if a substance given possesses or does not possess, to any degree whatever, the property of favoring the transformation of propepsin into active pepsin; in other words, if this substance is or is not pepsinogenic. Thanks to the preparatory repast, the stomach secretes all the pepsin that it is capable of furnishing in a single digestive period, and then remains for some time incapable of spontaneously secreting a peptic juice; in this condition it secretes, after the ingestion of an experimental repast deprived of the pepsinogenic properties, only a little gastric juice; this is acid, but apeptic, or nearly so; but if there are added to this experimental repast substances rich in pepsinogen, it soon gives out an abundant secretion rich in pepsin. Whatever may be the quantity of juice secreted in any given time, its amount of pepsin from first to last is uniformly small, if the animal has not received pepsinogens by mouth or anus. When, on the contrary, it has received them, the juice, at first scarcely peptic, becomes at the end of some time very rich in pepsin, the rate of which increases in proportion as the pepsinogen is absorbed into the blood. This increase is the more marked in proportion as the ingested substance is rich in pepsinogen and in proportion to its absorption. There is no relation between the digestibility of the nutriment and the amount of pepsin in the juice which is provoked by its ingestion. These principles must be of value in the treatment of functional troubles of the gastric mucosa.—*Revue Médicale de la Suisse Romande*, March 20, 1901.

A Case of Barlow's Disease Caused by the Use of Modified Milk.—G. Variot, after the study of this case which he reports, thinks that it is doubtful if the illness described by Barlow as infantile scurvy should be likened to the scurvy of adults. It is probable that it concerns a hemorrhagic rachitis. Hemorrhagic rachitis is a rare malady in France. A very few observations have been published since Netter's communication, and nevertheless the number of children who are fed on sterilized milk is very large. It is to be feared that modified milk predisposes to this affection: it is more often the cause than pure milk. The sickness, in spite of its alarming symptoms, does not appear to be very severe. Change of milk and alimentary régime works a rapid cure.—*La Tribune Médicale*, March 13, 1901.

Idiomuscular Excitability in Tabetics.—F. Duplant states that idiomuscular excitability in tabetics is most often normal, although it sometimes appears exaggerated. Muscular œdema is caused more easily in ataxics than in sound subjects. This reaction is only a variety of idiomuscular contraction; it is local in place of being generalized. The author believes that the apparent exaggeration of the idiomuscular reaction in tabes demonstrates the integrity of the muscles in the great majority of cases. The reaction obtained is not due to the excitation of the nervous filaments, cutaneous or muscular. The idiomuscular reaction in tabes is not stronger than normal, but it is rendered more apparent by the hypotony of the muscles, which is constant in locomotor ataxia.—*Lyon Médical*, March 24, 1901.

Deutsche med. Wochenschrift, March 28, 1901.

A Case of Nephrotomy for Renal Hemorrhage due to Unilateral Hemorrhagic Nephritis.—H. Laurent gives the history of a man aged fifty years, who for two years had suffered from intermittent attacks of hæmaturia. After urethral and vesical sources of bleeding had been excluded the cystoscope was used, and it was seen that the bloody urine came from the right ureter only. No local evidence of gross renal disease could be found, there was no tenderness or tumor, and no calculi or tubercle bacilli were present in the urine. Owing to the continuance of the hemorrhages and the patient's very advanced anæmia, operation seemed to offer the only hope, and the kidney was cut down upon by a lumbar incision. Nothing abnormal could be detected either in the external appearance of the organ or after incision, and examination of the ureter also gave a negative result. During his convalescence the patient's urine remained almost wholly free from blood, but erysipelas developed in the wound and caused his death one month after operation. At the autopsy a chronic nephritis of both kidneys was found, most marked in the right. Out of eighteen cases in the literature in which operation was done under similar conditions of renal bleeding without discoverable cause, in sixteen a permanent cure was effected. In ten of these the organ was removed, in five it was incised, twice it was loosened from its capsule, and once it was simply exposed. One case, a nephrectomy, ended fatally, and in another the hemorrhages recurred after a period of two months.

A Remarkable Case of Dissecting Aneurism of the Abdominal Aorta.—Ernst Fast reports this case in which the diagnosis was established before death. The patient was a man aged fifty years, alcoholic and used to heavy work, but non-venereal. For some years he had suffered from pain in the back and left thigh, which gradually increased up to the time of death, when it was agonizing. Important diagnostic points in the physical examination were pulsation below the right free costal border, not synchronous with the apical systole, hypertrophy and dilatation of the heart, accentuated aortic second sound, a loud diastolic murmur over the ensiform, and the fact that pressure on the two femoral arteries increased the loudness of this murmur. Aortic regurgitation could be excluded as a cause for this diastolic murmur, owing to the absence of peripheral corroborative evidence, and at the autopsy it was found to be due to the narrowing produced at the aortic opening in the diaphragm, owing to which the diastolic regurgitation from the aneurismal sack through the stenosis caused a murmur which was intensified when the tension was raised by pressure on the femorals.

Experimental Lumbar Puncture for Determining the Presence of Tubercle Bacilli.—H. Helleudall obtained lumbar puncture fluid from children having tuberculous meningitis, and injected it into the spinal canal of guinea-pigs with the idea of so producing an experimental meningitis in these animals. It was found, however, that although the animals speedily died, it was from tuberculous invasion in the spleen, liver, lungs, glands, etc., but that the meninges remained unaffected in every case. The infection was evidently carried directly by the lymphatics corresponding to the site of puncture, so that dissemination could take place much more rapidly and surely than from abdominal injections. The author therefore recommends this method of experimental infection for diagnostic purposes as affording prompter results and as being more likely to give a positive reaction when, as is often the case, the number of tubercle bacilli in the suspected fluid is very small.

Saponin and its Antidotes.—By F. Ransom.

The Göttingen Typhoid Epidemic of the Summer of 1900.—By P. Fraenckel.

Münch. med. Wochen., March 26 and April 2, 1901.

A Foreign Body in the Lung.—Although Spiess was unsuccessful in his attempt to remove a foreign body from the left bronchus by Killian's method of bronchoscopy, his experience was so encouraging as to lead him to believe that in suitable cases it gives the best chance of relief. In the case in question the difficulties encountered were due to the fact that the foreign body, a collar button, had been *in situ* for over four years. The patient's health had greatly suffered in consequence, and there was evidence of considerable inflammatory change in the lobe harboring the object. Through a tracheotomy wound it proved a simple matter to introduce an electrical bronchoscope by means of which the button could be seen and manipulated with instruments. The obstacle to extraction lay in the

fact that after perforating the bronchial wall the foreign body had set up an inflammatory reaction in the neighboring tissues, with the result that the opening through which it had once passed had become stenosed to such a degree that its exit was impossible. Various ingenious devices were employed to dilate the orifice and secure the button, but after several months of ineffectual effort the patient succumbed to the constitutional effects of the lung lesion. Instrumentation through the tracheotomy wound was sufficiently easy, however, to convince the author that in all recent cases it offers strong hopes of success, and that it should always be tried under such circumstances.

The Treatment of Contracted Pelvis in Labor by Version with Immediate Extraction.—W. Albert advocates in cases of moderate contraction of the pelvis, *i.e.*, with a true conjugate of 7 to 9.5 cm., that in primiparæ a spontaneous labor should be tried for, while in multiparæ version is indicated, though even here the possibility of unaided delivery is not to be lost sight of. In all these cases complete dilatation and unruptured membranes give the best prognosis, therefore dilatation with the elastic bag is in order. Later on, with primiparæ the membranes are to be ruptured and Walcher's position used; in multiparæ the same procedures are to be instituted even if only a segment of the head is well engaged; when the head is high or badly engaged immediate version and extraction should be done as soon as the os is fully dilated.

A Case of Aortic Aneurism Treated with Subcutaneous Gelatin Injections.—K. Barth describes a case in which a sacculated aneurism of the ascending aorta complicated by mitral insufficiency, emphysema, and bronchitis was very appreciably benefited by gelatin injections. The solution used was of one-per-cent. strength, and each course of treatment comprised twelve injections of 100 c.c. each, given on as many successive days. The site of injection was the lumbar region, and no pain or other disagreeable features were produced. All possible accessory measures were also employed: rest in bed, local cold, potassium iodide, and sparing diet, with the result that after the second series of injections marked subjective and objective improvement was noted.

Contributions to the Biological Identification of Human Blood.—A. Dieudonné publishes some results which corroborate the statements recently made by Uhlenhuth, Wasserman, Schutze, Stern, and Mertens. A number of rabbits were injected with human blood serum, albuminous urine, and pleural exudate respectively, and then their serum was added to human blood, nephritic urine, and pleural exudation, with the result that in each case a precipitate was obtained which was most marked when the type of serum was used which had been prepared by the injection of the particular body fluid that was to be tested. Corresponding tests on fluids of other animals gave negative results.

The Bloodless Treatment of Congenital Dislocation of the Femur.—C. Ghillini, with a material of one hundred successfully operated cases to base his observations on, concludes that the operation is really a curative measure and is deserving of universal application. When the head of the bone is above the acetabulum, the limb should be brought into a position of exaggerated abduction; when it is displaced downward it should be adducted; if the dislocation is backward the thigh is rotated externally, while if it is anterior internal rotation is necessary to effect reduction. Usually the deformities are not simple, but are combinations of the above positions; in such cases the appropriate manœuvres for reduction must also be combined.

An Unusual Case of Foreign Body in the Trachea.—G. Diehl's patient had already had two tracheotomies, one self-inflicted with suicidal intent, the other to relieve diphtheritic obstruction, with the result that cicatricial contractions made the permanent wearing of the tracheal tube a necessity. The tube habitually used by the patient was accidentally damaged, the protecting flange being broken, but was still worn till a new one could be procured, when in a fit of laughter it slipped out of reach down into the left bronchus. Efforts at removal by instrumental means proved unsuccessful, and a third tracheotomy was decided on, when the patient suddenly coughed up the missing object.

Urticaria with Albuminuria.—M. Günzburger reports a case in which a simple urticaria, apparently digestive in origin, was accompanied by œdema of the face and albumin in the urine. The patient was a boy aged thirteen, who on coming under observation presented the typical picture of an urticaria of moderate severity. The rash speedily disappeared under suitable therapy, when the persistence of the puffiness about the eyes prompted an examination of the urine, which was found heavily loaded with albumin. This finally disappeared after about two weeks, and as no other explanation for its presence could be found the author ascribes it to the urticaria.

The Auditory Organ and Equilibrium Control of the Japanese Dancing Mice.—Rudolf Canse says that the hypotheses which have been put forward to account for the erratic gyrations of these animals, and which ascribe their deficient sense of equilibrium to organic defects in the epithelium or bony structure of the semicircular canals, are erroneous. By careful comparisons of serial sections of the inner ear of these animals with similar preparations from the European house-mice he concludes that no important structural differences exist, and that the lack of space sense must be central, probably cerebellar, in origin.

The Etiology and Experimental Production of Cirrhosis of the Liver.—Markwald experimented on frogs and rabbits by giving them daily small amounts of antipyrin hypodermically. As a result well-marked cirrhosis was produced, this representing a reactive effort on the part of the organism against the primary destruction of the liver cells. The injection of larger amounts caused acute destruction of the liver. A further conclusion is that every substance having the property of destroying liver cells after long-continued action produces cirrhosis unless other extra-hepatic conditions are present to prevent.

Natural Immunization in Tuberculous Families.—A. Reibmayer believes that we are making a mistake in laying too great stress on the importance of artificially preventing tuberculous infection and not devoting enough attention to the preservation of the natural and inherited immunity that is to enable us to throw off the disease if it once gains entry into the system. It is impossible to carry out a perfect system of prophylaxis, and it is only by directing our efforts to the maintenance of perfect vigor by rigid adherence to hygienic rules that the disease can successfully be combated.

Clubbed Fingers.—F. Lacher contributes the history of a man aged thirty-two years, who for ten years had suffered from a suppurating pleural sinus the result of an empyema operation. The amount of discharge exciting suspicion, a foreign body was suspected, and subsequently located by a-ray examination. On operation it was found to be an old drainage tube, whose removal was followed by prompt subsidence of all constitutional symptoms and also a marked recession of the previously pronounced clubbing of the fingers.

The Effect of Coal on the Tubercle Bacillus.—J. Papasotirin tested the effect of various forms of coal and carbon dust on the tubercle bacillus by mixing varying quantities of these substances with the nutrient media. As the result of his observations he concludes that these bodies do not possess the inhibiting action on the growth of the bacillus commonly accredited to them.

Localized Congestions and Effusions in Heart Disease, with Observations on the Functional Diagnosis of Transition Forms between Exudates and Transudates.—By O. Rosenbach.

Report on the Ambulatory Department of the Clinical Institute for 1900.—By Kerchensteiner.

A Case of Mixed Cirrhosis of the Liver with Acute Course.—By H. Ullmann.

Report of the Medical Polyclinic of Munich for 1900.—By Moritz.

A Contribution to Multiple Fat Necrosis.—By Paul Ostermaier.

The Diseases of Chromate Workers.—By F. Hermanni.

Dr. August Brauser.—By W. Mayer.

Archives Générales de Médecine, April, 1901.

Cryptogenic Pyosepticæmia.—Amédée Pugnat holds that these mysterious instances of spontaneous pyosepticæmia are in many cases due to the presence of old cicatrices, which may be the starting-point of the disease, just as calcified tuberculous ganglia give rise to tuberculous granules, and slight attacks of osteomyelitis are sometimes followed at a later period by necrosis, fistula, and abscess. Infection may long be latent in these old cicatrices and then suddenly wake to renewed activity, manifesting itself either locally or generally. The author reports two demonstrative cases.

The Urinary Secretion in Syphilitics.—J. Patoir concludes that in certainly half the number of cases syphilis causes general nutritive disturbances at the time of the eruption. The liver and kidneys are thus affected, but not in benign cases. In young patients there is hyperactivity in elimination of urine. In the aged the opposite condition is caused. Specific treatment has a beneficial effect on impaired liver and kidney functions.

Clinical Study of Acute Broncho-Pulmonary Symptoms in Malaria.—By J. Crespin and R. Mailfert (conclusion).

Gastric Toxins.—By E. Cassaët (conclusion).

Reviews and Notices.

The American Year-Book of Medicine and Surgery, being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs, etc., collected and arranged with editorial comments by J. M. Baldy, M.D., C. H. Burnett, M.D., J. C. Da Costa, M.D., W. A. N. Dorland, M.D., V. P. Gibney, M.D., C. A. Hamann, M.D., H. F. Hansell, M.D., B. C. Hirst, M.D., E. F. Ingals, M.D., W. W. Keen, M.D., H. G. Ohls, M.D., Wendell Reber, M.D., J. H. Waterman, M.D., under the general editorial charge of George M. Gould, M.D. Two volumes, "Medicine" and "Surgery." Philadelphia and London: W. B. Saunders & Co. 1901.

This important work of reference upon contemporary medical subjects again appears in two volumes. The editors have evidently been at great pains to collect their material for reference, and the result is gratifying. The literature of all departments of medicine and surgery has been searched and analyzed and the results have been systematically collated, so that we are able in a very short time to tell just what has been done of any consequence in any branch, and where to look for more detailed information. The editors have made free comments, which are printed in brackets, and these add an element of interest to the work. The amount of labor involved in producing these volumes was enormous, and those responsible are to be congratulated.

An Introduction to Physiology. By William Townsend Porter, M.D., Associate Professor of Physiology in the Harvard Medical School. 12mo, pp. 314. Cambridge, Mass.: The University Press. 1901.

This title is slightly misleading as the book deals only with the physiology of muscle and nerve, and of the circulation. But, with this understanding, the book is worthy of attention. Its purpose is to train the student in the difficult art of simultaneous observation and reflection. To this end its pages are devoted to the description of the fundamental experiments of these sections of physiology, setting forth in clear, concise language the apparatus that is to be made use of, the manner of performing the experiment, and the object in view or *raison d'être* of the experiment. Some sixty diagrams accompany and elucidate the text where necessary. Although the book is intended for use in the laboratory where the student may be aided by the explanations of a professor, the apparatus required is comparatively inexpensive and the description of the experiments, from the simple nerve-muscle preparation to the more complex experiments in electro-physiology, is so good that any medical student can do them at home and derive great benefit from the work. The student who has performed them, who has added some reading to his work, will be in a position to study the other parts of physiology with more ease and a much clearer understanding of the subject; which object was the one that the author set out to accomplish.

An Introduction to Modern Scientific Chemistry. In the Form of Popular Lectures Suited for University Extension Students and General Readers. By Dr. Lassar-Cohn. Translated from the German by M. M. Pattison Muir, M.A. 12mo, pp. 348, with 58 illustrations. New York: D. Van Nostrand Co. 1901.

The presentation of a difficult subject in a form that is suitable at once for student and general reader is apt to be very difficult. In this case, if the general reader is willing to pardon a poor translation, the book is a good one. For the student, however, the text is unnecessarily wordy and the discussions of the theories of a hundred years ago concerning phlogiston, etc., are undesirable. Besides, it is of importance that, at the beginning of his studies, he call chemical compounds by their usual name and not say mercury oxide when every one else says mercuric oxide. The translation might have been more carefully done; there are many slips and also many passages of faulty construction. It is difficult to see the use of this book, for there are many better ones to be had on this subject.

Therapeutics: its Principles and Practice. By Horatio C. Wood, M.D., LL.D. Eleventh edition, remodelled and in greater part rewritten by Horatio C. Wood and Horatio C. Wood, Jr., M.D. Philadelphia and London: J. B. Lippincott Company. 1900.

The very fact that a book lives long enough to see eleven editions is proof that it has a *raison d'être*. There are comprised in this book an enormous mass of literature and many valuable suggestions. A point worth noting is that too little space and consideration are given to the employment of bromoform, and the authors would do well to look into the valuable service this drug renders in whooping-cough. We believe that distinct chapters on the therapeutic uses of dry cupping, and also the application of leeches, belong to a work of this kind, although the chapter on counter-irritants does not mention them. Still, the book contains about eight hundred and fifty pages of valuable information and deserves to be carefully studied.

Braithwaite's Retrospect of Medicine. Vol. CXXII. July–December, 1900. London: Simpkin & Co., Limited.

This volume is the same interesting compilation that we expect semi-annually. It contains many instructive abstracts and deserves to be studied. It is designed for ready reference and saves a great deal of time.

The Trained Nurses' Directory. Seventh edition. Compiled and edited by M. Louise Longeway, Graduate of Bellevue Training-School.

This very useful work is designed for physicians and families who may need the services of graduate nurses who have been specially selected and recommended by leading physicians and surgeons as having had "requisite hospital training and subsequent practice in private duty." The names are alphabetically arranged, giving addresses, telephone number, school, year of graduation, and the special cases taken by the graduates doing private duty in New York, Brooklyn, Albany, Orange, N. J., Pittsfield, Mass., Hartford, and New Haven, Conn., and the towns adjoining those cities.

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia; Member of the Academy of Natural Sciences of Philadelphia; Member of the American Medical Association, etc. Second edition, enlarged and thoroughly revised. Illustrated with 77 engravings. Philadelphia and New York: Lea Brothers & Co. 1900.

The appearance of the second volume of this work is a practical proof of the favor with which it has met. The original edition has been carefully and thoroughly revised, while a chapter on military hygiene—most appropriate at this time—has been added. The text is made clear and attractive by numerous illustrations. The book is useful not only as a text-book, but as a general work of reference on the subject treated. Among the chapters are those on personal hygiene, disinfection, and quarantine, the removal and disposal of sewage, vital statistics, and the examination of air, water, and food.

Sexual Debility in Man. By F. R. Sturgis, M.D. Author of "Student's Manual of Venereal Diseases"; one of the authors of "A System of Legal Medicine." New York: E. B. Treat & Co. 1900.

The author of this well-written study of debility depending upon or associated with sexual diseases and excesses is surely facetious in his dedication and preface. The spirit of frankness and lack of cant strikes the fancy at once, and the sentiment which inspired the inscription of the book to "the sexual cripples who have contributed to the writer's support" appeals to fair-minded men as tempered with justice no less commendable because unusual. The work is in many respects original, giving the writer's peculiarly personal views upon various questions, which are somewhat at variance with those held by the majority of authors. The pages show a wide experience in these matters. Spermatorrhœa and pollutions are treated of as separate conditions of distinct nature. The former is looked upon as a disease *sui generis*. The views upon masturbation and its consequences do not differ essentially from those now entertained by suitably enlightened physicians, but do differ materially from those found in quack literature so freely distributed to the innocent and ignorant youth of the country. The work is honestly written in the good faith of conviction.

Diseases of the Nervous System. A Text-Book for Students and Practitioners of Medicine. By H. Oppenheim, M.D., Professor at the University of Berlin. Authorized Translation by Edward E. Mayer, A.M., M.D., Pittsburg, Pa. First American from the second revised and enlarged German edition. 8vo, pp. 899. Philadelphia and London: J. B. Lippincott Co.

In the German edition from which this is translated there were made a number of changes and additions which brought the work well forward in the ranks of text-books upon this specialty. Treatment especially has been improved upon by reason of various recent scientific advances, so that the work as it is now presented to English readers is decidedly better than was the original text. The illustrations have been increased in number. Some

are not all that one might expect, from an artistic, photographic, or accurately scientific aspect. For the most part, however, they serve the intended purpose of showing at a glance what whole pages could not so well convey to the mind. Many inserted cuts are necessarily but schematic aids to the student or reader. For a nerve book it may be said to be profusely illustrated. The popularity of the work abroad has been the incentive to its American translation, and, with the exception of a few minor changes, the text stands as written, and the translator is to be congratulated on his work.

Lea's Series of Pocket Text-Books. Obstetrics. A Manual for Students and Practitioners. By David James Evans, M.D., Lecturer on Obstetrics and Diseases of Infancy, McGill University, Montreal, Canada; Fellow of the Obstetrical Society, London, England. Series edited by Bern. B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York; Visiting Surgeon, Bellevue Hospital, New York. Illustrated with 149 engravings. Philadelphia and New York: Lea Brothers & Co. 1900.

This new member of the "pocket text-book" series bears out the reputation of those which have preceded. The author has taken up the physiology of pregnancy, of labor, and of the puerperium quite fully, before he considers their pathology. The ordinary problems which confront the obstetrician are dealt with quite in detail, while the more abnormal conditions and complicated operations are touched on more lightly. The book is particularly fitted for the use of undergraduates and young practitioners, being very clear and concise.

Manuel d'Histologie Pathologique. By Professors Cornil and Ranvier, with the collaboration of Drs. Brault and Letulle. Third edition. Vol. I. Octavo, pp. 910. Paris: Felix Alcan. 1901.

The first volume of this work introduces us, as we expect very naturally from such authors as Cornil and Ranvier, to a clear, careful, thorough treatise on pathological histology. Each part is brought up to date and is the last word of microscopical research on the subject. Each chapter of pathology is preceded by a description of the normal histology and each is closed by an abundant bibliography. In order to make the work a complete one, the authors have availed themselves of the services of a number of collaborators; the work, however, is homogeneous, as all of this aid is from men who have worked for years in the laboratories of Cornil and Ranvier, and are imbued with their ideas and traditions. This volume presents a general introduction to normal histology by Ranvier; and the same for pathological histology by Cornil, who gives us also a study of the inflammations. Then we have a chapter on tumors, by Brault, and one on parasites, including bacteria; another on the lesions of bone and of cartilage, by Cazin, and the book closes with one on changes in connective tissue and lesions of the serous membranes, by Cornil. Each subject is plentifully and beautifully illustrated with original plates in black and in colors, many of which will doubtless find their way into numerous books as examples of perfect illustrations in normal and pathological histology. In the chapter on inflammations are to be found Ranvier's recent researches on the clastmatocytes. In studying the origin of the leucocytes that are present about an inflamed area, Ranvier has found that, besides the leucocytes that arise from the multiplication of those that are already present, and of others that have come from the blood-vessels by diapedesis, very many are formed at the expense of the clasmatocytes. He has given the name of clasmatocyte (*κλασμα*, fragment) to an irregularly narrow and long histological element, sometimes 100 μ in length, composed of fragments of finely granular substance held together by filaments and having an ovoid nucleus. The connecting filaments may be coarse, may be so fine as to require a high power, or may disappear, leaving the fragments spread about in the connective tissue. Clasmatocytes are most numerous and may be best observed in the connective tissue and serous membrane of urodela, batrachia anura, and small mammifera; as many as a hundred per square millimetre may be counted in the peri-œsophageal membrane of the rana temporaria. They show no amœboid motions and yet they are derived from white blood cells which have travelled from the blood-vessel into the connective tissue. Ranvier has seen all stages of transformation of the leucocyte into the clasmatocyte. The latter, whose granular, fragmentary protoplasm represents the substance of a leucocyte which has been fixed in the connective tissue, can return to the embryonic stage and be again a leucocyte under the influence of inflammation. It may then multiply by direct division as any other leucocyte. We find Ranvier's fine work and excellent plates again in a study on the healing of wounds of the cornea.

In the chapter on tumors, the author (Brault), discussing the parasitic theories of tumors, expresses the opinion that before we can leave the present sterile period of research, new methods are indispensable, and that the technique of to-day has said its last word. The chapter is closed by an excellent bibliography. The histology, normal and pathological, of serous membranes assumes a peculiar interest in view of the publications of Widal upon the cytodiagnosis of the nature of pleuritic effusions. This work of Cornil and Ranvier would be a valuable addition to the English literature of the subject and is worthy of an able translator.

Obstetric Clinic. By Denslow Lewis, Ph.C., M.D., Professor of Gynæcology in the Chicago Polyclinic Hospital, Chicago; President of the Chicago Medical Examiners' Association; Vice-President of the Illinois State Medical Society; ex-President of the Physicians' Club, of Chicago; Consulting Obstetrician to the Florence Nightingale Home; Senior Gynæcologist and Obstetrician to the Lakeside Hospital, Chicago; late Special Commissioner from the State Board of Health of Illinois and the Health Department of Chicago for the Investigation of Municipal Sanitation in European Cities. A Series of Clinical Lectures on Practical Obstetrics Delivered to Students and Practitioners in Cook County Hospital, Chicago. Together with Remarks on Criminal Abortion, Infanticide, Illegitimacy, the Restriction of Venereal Diseases, the Regulation of Prostitution, and other Medico-Sociologic Subjects. Chicago: E. H. Colegrove. 1900.

This volume is a stenographic compilation of thirty-nine lectures of the author, as they were given in the class-room from day to day. Consequently, the style is conversational and particularly interesting. The reader absorbs much valuable information with the slightest expenditure of effort. The writer treats the subject of obstetrics in its entirety in a useful and practical manner, including the consideration of gonorrhœa and syphilis and certain sociologic problems related to these subjects. The work is provided with an excellent index and cannot fail to be a valuable addition to any medical library.

International Clinics: A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose, and Throat, and Other Topics of Interest to Students and Practitioners, by Leading Members of the Medical Profession throughout the World. Edited by Henry W. Cattell, A.M., M.D., of Philadelphia, with the collaboration of John B. Murphy, M.D., of Chicago; Alexander D. Blackader, M.D., of Montreal; H. C. Wood, M.D., of Philadelphia; T. M. Rotch, M.D., of Boston; E. Landolt, M.D., of Paris; Thomas G. Morton, M.D., and Charles H. Reed, M.D., of Philadelphia; with regular correspondents in Montreal, London, Paris, Leipsic, and Vienna. Vol. IV., tenth series. Philadelphia: J. B. Lippincott Co. 1901.

This volume contains, besides the usual chapters on therapeutics, medicine, neurology, pathology, etc., a symposium on genito-urinary diseases, by Renault, Pedersen, Guyon, Ohmann-Dumesnil, and Fournier. There is also a monograph by H. W. Cattell, the editor, on the etiology and morbid anatomy of various diseases. There is a frontispiece colored plate illustrating Professor Roncali's article on the rôle of blastomyces in cancer. The photographic illustrations which have made previous volumes attractive are noticeably absent. For a clinical journal intended largely for those who are deprived of seeing clinical cases in large cities the aim should be to supply as many clinical pictures and as few histological illustrations as possible.

A Manual of Materia Medica and Pharmacology. Comprising all Organic and Inorganic Drugs which are and have been Official in the United States Pharmacopœia, Together with Important Allied Species and Useful Synthetics, especially designed for Students of Pharmacy and Medicine, as well as for Druggists, Pharmacists, and Physicians. By David M. R. Culbreth, Ph.G., M.D. Second edition, enlarged and thoroughly revised, with 400 illustrations. Philadelphia and New York: Lea Brothers & Co. 1901.

This edition has undergone the usual amount of making over and insertion of such called-for additions as will bring the work abreast of the times. In this manual the aim has been to keep associated such substances as have a common or allied origin. The author has taken the initiative in this country in applying this order to organic and inorganic remedies, keeping the basal or parental source paramount. The modern nomenclature has become necessary

on this account, and that fad proves at times awkward, as the author states, because it conflicts with the last pharmacopœia. Animal drugs are considered in the order of zoological sequence. The metric system is employed, but the English equivalents are given. Prescription writing is treated in a new chapter, and there are a number of new illustrations. These changes are in keeping with the aim at utility and help to maintain the high character which the first edition manifests.

Primary Echinococcus Cysts of the Pleura. Report of a case of primary exogenous echinococcus cysts of the pleura, showing hyaline degeneration of the cuticle without lamellation, with notes of the literature. By Charles Cary, M.D. and Irving P. Lyon, M.D., of Buffalo, N. Y. 1900.

Our Teeth, and How to Take Care of Them. By Victor C. Bell, D.D.S. New York: Young America Publishing Company.

This little volume contains a series of questions and answers, and is admirably adapted to instruct those unfamiliar with the elementary knowledge of the teeth.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

COURT APPOINTMENTS—PARLIAMENT—VACCINATION—LONDON WATER QUESTION—ADJOURNED DISCUSSION ON RHEUMATISM—PERNICIOUS ANÆMIA—ANTIVIVISECTIONISTS—PUBLIC HEALTH.

London, April 5, 1901.

The court medical appointments have been gazetted. They are largely re-appointments, for most of the gentlemen served in the same capacity either the late Queen Victoria or Edward VII. when Prince of Wales. A new office seems to be honorary anæsthetist to the King—it is given to Dr. Hewitt.

In the House of Commons the isolation hospitals bill and the cremation bill have passed the second reading. The latter has previously gone through the Lords.

Sir John Rolleston, as member for Leicester, questioned the secretary of the local government board about the vaccination prosecutions taking place in that town. He was told that the local officer had been reminded of his duty to institute them.

Another attack on vaccination has been made, but is likely to prove disastrous to the leader. Lieutenant-General Phelps has written a letter to *The Times* in which he quotes the ex-medical officer of Glasgow as saying, in reference to a former epidemic, "Vaccination and revaccination have conspicuously failed to keep the enemy at bay." He has not verified his reference. Military methods may permit deliberate deception of the enemy, but controversy is another thing, and the lieutenant-general should learn that the first object of science is truth. If he states what is obviously false, he may be convicted of taking a position which is not one for an "officer and a gentleman" to occupy.

Mr. Long has curtly refused to state the government proposals as to London water before the close of the session, so that the public may have time to consider them during the recess. This will not tend to restore the confidence of the London ratepayer, who feels he has not obtained the end for which he returned the new county council. It is quite possible this water question may seriously shake the government.

The adjourned discussion on the relationship of the various rheumatic affections developed some further differences of opinion. It was resumed in a paper by Dr. Bannatyne, of Bath, who said that the rare cases in which rheumatoid arthritis seemed set up by acute infective rheumatism were, he thought, instances of one disease engrafted, so to say, on the other. Statistics showed that rheumatoid arthritis often followed other diseases—perhaps as often as rheumatic fever. The chronic form of rheumatoid arthritis followed a different course, and might be considered degenerative and secondary to any joint trouble. He and Dr. Wohlman had found in one form of rheumatoid arthritis a micro-organism which differed in character and life-history from that described by Drs. Poynton and Paine.

Dr. Hewlett had isolated a bacillus resembling the Achalme bacillus. He thought the organism isolated by Dr. Bloxall differed from that described by Drs. Poynton and Paine. Identity of clinical symptoms and almost indistinguishable pathological appearances did not prove identical etiology. Toxæmias were apt to affect joints, and arthritis was met with in scarlet fever, influenza, dysentery, and other diseases. He agreed with Dr. Bannatyne that the rheumatoid condition was grafted on the rheumatic one.

Mr. A. Lane held that rheumatoid and osteo-arthritis were terms often used to cover various conditions produced by traumatism and having no relation to any rheumatic affection. Their causation was simply mechanical. The terms "rheumatic affections" and "chronic rheumatic" were unmeaning apart from true rheumatoid arthritis.

Mr. Armstrong held that so far as present knowledge went there was no common origin of rheumatic and chronic joint affections. He thought it improbable that all cases of rheumatoid arthritis were due to bacteria; it was more probable that the disease was a dystrophy due to central nerve disturbance or to reflex irritation from other organs.

Dr. Paine did not think it possible at present to speak definitely about the toxins of the organism found by Dr. Poynton and himself, for they really knew but little about the organism. Many of the early symptoms might be due to chill and others to absorption of toxins. Dr. Newsholme had found rheumatism on dry soils more frequently than on clay.

Dr. Blanc, of Aix-les-Bains, said rheumatoid arthritis might arise from causes unknown, and it might be set up by rheumatic fever, though perhaps oftener not. He asked if the members present thought they ever cured true rheumatoid arthritis.

Dr. A. Garrod made some remarks on the views elicited, and said in his opinion the diplococcus of Drs. Poynton and Paine brought them to the pathological cause of acute rheumatism, and would serve to differentiate that from the other affections. He felt they were only just beginning to learn something about the conditions grouped under the term "rheumatoid arthritis."

Sir D. Duckworth confessed to a belief in diatheses. Many gouty deformities were indistinguishable from those of rheumatoid arthritis. Exostoses and ankyloses found in gout were significant. Nodules he was disposed to regard as indicative of an arthritic diathesis. Many chronic joint cases following acute rheumatism were due to the patient's strumous diathesis. They were not easy to differentiate, as no doubt some cases of rheumatoid arthritis were brought on by acute rheumatism and others came on after acute articular gout with no rheumatic antecedents. It was not easy to deny that a blended condition of true rheumatism and true gout might exist, but the conditions leading to it were not identical. Neuro-arthritic conditions must be considered. No one definite cause could be made to include all cases of rheumatoid arthritis.

Dr. William Hunter's investigations on pernicious anæmia will in some points be familiar to you, as he has been carrying them on for about fifteen years. He has now been able to apply the treatment which his researches led him to propound—and that with success. He therefore brought the case before the Medico-Chirurgical Society at its last meeting in an elaborate paper giving an account of his views, and illustrated with lantern slides. The case showed the typical mode of development and the four clinical groups of symptoms, viz., extreme weakness and anæmia; the red corpuscles decreased to twenty-seven per cent. of the normal and the hæmoglobin to thirty-five; hæmolytic manifestations, as urobilinuria and lemon-colored skin; oral and gastro-intestinal symptoms; toxic symptoms. The result of six weeks' treatment was an increase of forty per cent. of red corpuscles and thirty-seven per cent. of hæmoglobin, and the progress was afterward steady.

Dr. Hunter concludes from his investigations that pernicious anæmia is a definite infective disease, localized in the mucosa of the alimentary canal, causing a most definite and characteristic group of effects, both clinically and pathologically, which admit of its being distinguished during life and after death. In this infection oro-gastro-intestinal sepsis plays the most important part. These views, you will notice, are very different from those of previous observers, inasmuch as their basis is pathological rather than clinical. They are deduced from Dr. Hunter's researches on hæmolysis and the portal circulation. From them he formulates the following definition: Pernicious anæmia is a chronic infective disease localized in the alimentary tract, caused by a definite infection of certain parts of the mucosa of the alimentary tract, chiefly of the stomach, occasionally also of the mouth and of the intestine. In the infection, sepsis, both oral and gastric, plays an essentially important antecedent and concurrent part. It is characterized by (1) intermittent destruction of blood and increasing anæmia (and all consecutive changes, pathological and clinical, *e.g.*, anæmia, lemon color, urobilinuria, hemorrhages, dyspnœa, palpitation, œdema) as the result of the absorption of poisons into the blood and their hæmolytic action; (2) periodic disturbance of the alimentary tract, chiefly of the stomach and the intestine, as local effects of the infection; (3) occasional toxæmic attacks, characterized by fever, sweats, and general nervous symptoms; not infrequently numbness, tingling, ataxia, absence of reflexes denoting deeper

nervous changes, such as peripheral neuritis or sclerosis of the cord.

The frequency and importance of the gastro-intestinal disturbance have led to misapprehension in some quarters where the terms gastro-intestinal "nature" or "origin" or "cause" are spoken of. But this is not Dr. Hunter's view at all. The significance of the symptoms is that they show the gastro-intestinal site of the infection which is the cause of the disease.

The indications for prevention and treatment flow naturally from the theory advanced by Dr. Hunter. They are: (1) Oral antisepsis, with reference to diseased teeth and lesions of the tongue; (2) gastric and intestinal antisepsis, of which the oral treatment is an important part; (3) arsenic. This last alone cannot permanently arrest the disease, though it may increase the duration. If these measures, carefully carried out, fail, Dr. Hunter recommends antitoxic treatment in order to antagonize in the blood the poisons producing the hæmolysis. In the case related he resorted to this measure and injected streptococcic serum four times in the course of five weeks. This is not substituted for, but in addition to, the antiseptic and arsenical treatment.

The paper was followed by a few remarks, scarcely amounting to discussion. Dr. Coupland congratulated Dr. Hunter on lifting the veil of a mysterious disease by his patient researches, and leaving only the demonstration of the special poison to complete the work—for a special poison there must be, as pernicious anæmia is so rare and oral sepsis so common. Dr. Reissman asked if any special blood change existed which would settle the diagnosis during life. He had seen two cases, believed to be pernicious anæmia, prove at the post-mortem to be colloid cancer of the stomach. Mr. Bokenham asked if the author had shown the specific cause by cultivations. Dr. Saville thought neurasthenia was often due to the state of the teeth. Mr. Barker had seen Dr. Hunter's case, and the intestinal symptoms obscured those of the mouth. He suggested that the blood in some cases of alveolar abscess might be investigated with advantage.

Dr. Hunter replied that he had not yet isolated the specific organism. He had seen ten other cases since the one he had described. The diagnosis could not be based on blood changes alone, but on the four groups of symptoms he had pointed out—anæmia, hæmolytic changes in the urine, oro-gastro-intestinal symptoms, fever with toxæmic symptoms. The streptococcus was only an associated organism, as it was not hæmolytic.

A letter in the daily papers proclaims that a lady has revoked a bequest to hospitals on account of her belief that they have vivisectors connected with them. The writer does not seem conscious of the injustice thus done to suffering patients, but rather gloats over the success of the faddists who started a campaign against hospitals for suffering human beings, and carry on their little war with humanity by the circulation of misstatements.

The mortality returns continue to be favorable in spite of the severe and variable weather we have experienced. The death rate of London for the past four weeks has averaged 18.3, which is 3.3 below the decennial average. Measles and whooping-cough have been rife, and some sanitarians are again calling for notification, but others are doubtful about this measure and the public is not prepared for it. The country mortality has also kept low. The Glasgow epidemic of smallpox is declining under the influence of revaccination, and it is hoped will be over before the exhibition opens. At Cardiff four cases of smallpox were brought in a vessel and three persons became infected. They have been isolated and a watch has been kept over contacts.

NOTES ON A NEW METHOD OF STAINING THE CANCRIAMŒBÆ IN CARCINOMA.

To the Editor of the Medical Record.

Sir: Since the publication of my paper on the parasitic amœbæ in carcinoma (Medical Record, July 7, 1900), I have succeeded in greatly improving the method of staining the sections in such a manner as to eliminate as much as possible the personal skill required in manipulation. For the benefit of those who have no time to refer to my first article I will recapitulate the method of fixing, etc.

The tissue is cut from the growing part of the carcinoma somewhere near the edge of the tumor. The piece should in no instance be larger than one-quarter inch in diameter. While yet warm from the natural body heat, if possible, and immediately after cutting away the piece, it is dropped in a solution of chemically pure bichromate of potassium three per cent., glacial acetic acid six per cent., and water ninety-one per cent. The liquid should, if possible, have the body temperature, which can easily be accomplished by keeping the small vial in the inner pocket of the coat or in an incubator. After a few hours (two to twenty-four) the piece is taken out of the fixative and placed in running water until the yellow color of the tissue is extracted, which generally takes twelve to twenty-four hours. The tissue is now passed through the alcohols into Squibb's absolute alcohol, thence into chloroform-alcohol, thence to pure chloroform. Instead of chloroform, xylol or bergamot oil will answer. The tissue goes next into chloroform-paraffin, then in pure paraffin. The sections should be cut not over 6 μ thick, as otherwise the amœbæ cannot be differentiated by staining. The sections are placed on the slide, which latter is flooded with alcohol of eighty per cent. The slide is then lightly warmed until the sections suddenly stretch out, which takes only a few seconds. If the heat is so great as to melt the paraffin, the sections contract and become useless. Next the sections are pressed down on the slide by a piece of blotting-paper wet in alcohol. Considerable pressure is required, and there is no danger of injuring the sections through the pressure. The slides should be dried for fifteen minutes to several hours, or until the sections become rather transparent, when they will stick to the slide permanently. The paraffin is now removed by xylol, which latter is at once washed off with strong alcohol. The slide is to be placed at once in a jar containing a solution of thionin, one per cent., in water. The best thionin for this purpose is the one of the Berliner Actien-Gesellschaft. Ten per cent. of alcohol may be added to the thionin in order to prevent fermentation. The slide is to be kept in thionin for twelve hours or more, taken out and rinsed quickly in running water, but the water kept from striking directly on the sections. A few seconds will suffice to wash off the superfluous thionin. A solution of eosin soluble in alcohol of ninety-five per cent. should be ready. The slide is held with the left hand, slanting, and with a dropper the slide is flooded with the alcoholic eosin. In a few seconds it is seen that the eosin is washing off the thionin and the sections are changing from blue to reddish-violet. When they assume the latter color, they are immediately flooded with absolute alcohol by means of a dropper. The eosin is thus washed away quickly. This takes only a second or two. Then the slide is flooded with bergamot oil, which latter may be washed off with xylol. The slide is now mounted in xylol-balsam, or, better yet, in "xylol-thus." To stain the slide after it is once taken from the thionin bath requires only a few seconds to a minute. If prolonged, the thionin will be washed out too much and the differentiation will be less good. In holding the slide up to light it should have a reddish-violet tint. The tissue is now stained red. The cancriamœbæ are deeper red, with their nuclei dark blue, while the nuclei of the tissue cells are much lighter blue. The amœbæ being much darker stained show up with facility, and even their pseudopodic projections penetrating into the tissue cells are readily seen with a good oil immersion.

I may add that since publishing my first paper I have found the amœbæ in some thirty odd cancer tissues, or in every cancer tissue examined, and have studied and observed the development of the amœbæ from the spore, the latter occurring in large quantities in many tissues, especially in the lymph ducts.

Gustav Eisen, M.D.

THE PROPER SOLUTION OF THE SPITTING NUISANCE.

To the Editor of the Medical Record.

Sir: Permit me to call the attention of many interested readers through the columns of your valuable journal to the decision rendered by Magistrate Healy, of Flushing, L. I., April 13, 1901. He held "that two men who had been arrested for expectorating on the floor of the Long Island railroad depot at Flushing were guilty of no violation of the sanitary code, because it was the duty of the railroad authorities to provide cuspidors." That is, in my opinion, as it should be. And in connection with this decision I beg to cite a passage from my remarks on the same subject printed in your columns December 25, 1897, where I said: "There was a crying need to spare the community from the spitting nuisance, but half measures are no measures. To enact ordinances without offering adequate means to carry them out is to educate citizens to violate the laws unwillingly. And the remedy is so simple"; by which I meant, providing depots, surface and elevated cars with properly adjusted receptacles for expectorated matter, and filling them with antiseptic fluids; these cuspidors should be replaced with fresh ones at the end of each trip.

I hope this decision will serve the purpose of a test case,

and as a reminder to other courts and to the New York board of health as well, that before they impose heavy or light fines upon citizens for violating the sanitary code in this particular, they should stop a moment and ask themselves whether or not any receptacles were on hand at those places to enable the so-called offenders to abide by the laws enacted. Do not fine them otherwise! It is illogical and unjust!

I heartily congratulate Magistrate Healy upon the wisdom manifested in his decision. HENRY LEVIEN, M.D.

LIBERTY, N. Y.

SPINAL COCAINIZATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: To replace the longer term spinal cocainization, I would suggest naming the process "Corningization." To "Corningize the cord" would be a term both euphonic and appropriate. CHARLES W. ALLEN.

30 EAST THIRTY-THIRD STREET, NEW YORK.

PILL-SCRATCHING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Under this homely caption the writer would suggest to his fellow practitioners the importance of a simple precaution in the use of coated pills which he has for some time taught to his patients: "Scratch all coated pills, and make a pin-hole in the ends of all capsules." It is a process which takes little time and trouble; yet may make all the difference between success and failure in precarious conditions of illness. All pills and hard capsules are intended to be, and supposed to be, soluble; but we know that some are not quickly dissolved. They are either dissolved at an unknown rate of tardiness, or may even pass out by rectum (both pills and capsules) untouched by the digestive juices. The danger is, not that this occurs, but that we do not know when it will occur. If we knew, we could at that time confine our medication to bare drug-masses or liquids. As we do not know, it is wise to guard against possible non-solution of the pill at all times by breaking through its coating before it is given.

Coated pills may or may not be soluble in normal stomach juices. They may have been freshly bought by the druggist, yet have lain for years in the manufactory. There is certainly great difference in the hardness of even gelatin-coated pills of the same formula from the same first-class maker, as tested by the writer. Into some the knife-point sinks easily; others are difficult to cut. It is hardly necessary to state that sugar-coated pills vary as much or more in solubility. The writer has known of samples which had to be boiled before they would dissolve.

It may be urged that in the stomach and bowels the pills are subjected to various chemical solvents other than water. But here is one of the greatest causes of uncertainty! We do not have to deal in sickness with normal digestive juices. These juices may be so changed or so diluted that they have hardly any solvent power at all. Even the most easily digestible particles of food will in many conditions remain unchanged in the canal; even ready-made pills may in some cases lie for hours undissolved. In cases not so extreme as these, the intact coated pill may well go on its journey as artistically complete as when it began.

Since coated pills are convenient and will be used, it is wise, by scratching through their coating with a penknife or scissor-point, to make them as open to attack by the digestive juices as are fresh-made pills.

There is another possibility to which the writer refers with diffidence, through want of personal experience. There have been ulcerated appendices found with intact or partly dissolved coated pills in them. This is considered by some a coincidence or consequence, not a cause of the ulceration. Surely, however, if there is a lame or sore appendix, as in many cases of bowel debility, it is not desirable that undissolved pills which will exactly fit into the enfeebled pouch should be travelling in the vicinity of its mouth. A coincidence, in such a case, may bring a consequence, and a consequence might be a furthering cause of a condition in these days too sadly frequent.

Scratch your pills, doctor! Tell your patients that they must do it if they wish to get the best drug effects, and would even be wise to perforate their capsules. Your thoughtful patients will need to be told of it but once, and will feel that such carefulness for results betokens the sort of doctor that they want as their health guardian and champion in disease.

But don't tell them about the appendix!

A. K. BOND, M.D.

BALTIMORE, April 19, 1901.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 18, 1901.

ROBERT F. WEIR, M.D., PRESIDENT.

Dull and Deficient Children.—This was the topic for discussion, and it was in the charge of the section on pediatrics.

Introduction to the Psychological Study of Deficient Children.—DR. WILLIAM B. NOYES presented this opening paper. He spoke of the desirability of dividing children, for the purposes of education, according to their susceptibility to suggestion into the following classes, viz.: (1) Children of an automatic type—the average good school children; (2) sensitive children who responded most readily to appeals to their emotional nature; (3) children who were mentally bright and had a well-marked individuality, but who were best controlled by arousing in them a spirit of opposition; (4) a class characterized by obstinacy and rebelliousness to suggestion, *e.g.*, the undisciplined and insubordinate, and morally perverse and degenerate. To this classification some would add a fifth class, comprising children whose suggestibility was abnormal, as seen, for example, in those of a hysterical temperament. Another method of classifying mentally defective children was this: (1) Those in whom the faculty of perception was defective, *e.g.*, in the deaf, dumb, and blind; (2) those who lacked the power of attention, though possessing normal special senses; (3) those exhibiting a defect or a diseased state of the will; (4) those having deficient reasoning-power, and (5) morally defective children.

Etiology of Mental Deficiency.—DR. PEARCE BAILEY read a paper on this subject. He said that mental deficiency was conveniently divided into three forms, viz.: (1) That form occurring before birth; (2) that occurring at birth, and (3) that variety which developed in infancy. As feeble-minded women fell an easy prey to venereal disease and to the lust of men, and particularly as their progeny were almost always idiotic, the policy of the State to protect these women by keeping them in State custodial institutions seemed to be eminently wise and humane. As to the influence of alcoholism, his experience was that the offspring of alcoholics were apt to have disordered nervous systems, but among them idiocy was not especially common. Active syphilis in one or both parents was reflected in the offspring. He deplored the present almost total lack of any restrictions on the marriage of persons who were mentally and physically totally unfit for this social condition. During the first two or three weeks of life it was not possible to decide as to whether or not the mentality of an infant was normal, yet the necessity for discovering mental defects as early as possible was obvious if one would but recall the fact that the brain grew very rapidly in early life, weighing at the end of the second year three times what it did at birth. Convulsions undoubtedly arose in infancy as a result of a great variety of reflex irritations, and he was of the opinion that if they occurred sufficiently often the epileptic habit might be formed. This seemed to him to afford a reasonable explanation of the origin of many cases of so-called idiopathic epilepsy, particularly when there was a perfectly good family history.

Dulness due to Eye Defects.—DR. CHARLES STEDMAN BULL took up this topic. He said that defective vision was a very common cause of apparent mental dulness in young children. The hypermetropic child found difficulty in sustaining the accommodative effort necessary for near vision, and hence soon appeared to

be slow and stupid, but this apparent stupidity would quickly disappear on proper correction of the refractive error. Astigmatism was another common visual defect, but by far the most important refractive error, and one which was rapidly on the increase, was myopia. It had been found that the number of short-sighted pupils increased from the lowest to the highest grades in school, and in direct proportion to the number of hours of study. He would commend this curse of modern civilization to the earnest consideration and study of sanitarians. The mental evolution of these myopic children was instructive. They were apt to become introspective and perverted in their tastes; but if the error were corrected and also the bad habits of life resulting from this defect, a new world would be opened to the unfortunate, and he would quickly dispel any doubts as to his mental capability. Most of the insufficiencies of the ocular muscles were associated with refractive errors, and were often responsible for headache and eye-ache, vertigo and diplopia. Defects of vision also arose from the following congenital anomalies of the eyes: (1) Congenital cataract; (2) dislocation of the lens, (3) more or less marked absence of pigment in the uveal tract, notably in the iris; (4) coloboma or fissure of the iris or choroid, or of both; (5) entire absence of the iris. There were also cases of congenital word blindness and of congenital lack of visual memory. Such children could be decidedly improved by an early and persistent use of methodical instruction in reading.

Function of the Teacher in Discovering and Treating Mental Deficiency.—Prof. Lightner Witmer, of the University of Pennsylvania, discussed this topic. He thought that the teacher was more favorably situated than the physician for detecting mental deficiency in children. He had never met with a case of chronic bad spelling in which he had not also found some visual defect. He believed that full one-tenth of the time and effort of teachers was taken up in the endeavor to teach those who were mentally backward. The remedy suggested was to divide the mentally deficient into two classes, the intellectually and the morally defective, each class having its specially trained teachers.

The City's Obligation to Provide Special Education for Defective Children.—Superintendent C. E. Meleney, of the board of education, discussed this question. He said that, according to the census of 1890, there were 97,000 feeble-minded or idiotic persons in the United States. There were nineteen State institutions for the feeble-minded, two in our own State. Marvellous results had been obtained in these institutions, and these alone constituted a cogent argument for providing adequate special instruction for defective children. There were at present enough such pupils to warrant the establishment of special classes for them in this city, but the greatest obstacle to such a change was the unwillingness of parents to admit that their children were backward or mentally deficient. He was in favor of establishing such special schools or classes, as a part of the public-school system, and placing in charge born teachers who had received special training for this work. There were five such public schools in the city of Providence. It was a great mistake, but one too often committed by parents, to neglect to educate these defective children when small, for the loss in these early years could hardly be made up afterward. The children should be kept as far as possible in a natural environment, and thus accustomed to the surroundings amid which they must spend their lives. For this reason he was opposed to placing such children in large institutions.

Dr. Leroy M. Yale said that he made it a rule not to blame a school for a child's failure to progress satisfactorily until a careful examination had excluded defects of the special senses or had revealed decided mental impairment. He had been particularly impressed with the existence of distinct types of development in certain families. It was no uncommon thing for parents who had been slow and dull in childhood, but who had subsequently developed and had become bright and successful citizens, to expect that their children should be bright and quick at school, having apparently forgotten their own mode of development. He deprecated the tendency displayed by our department of education to spend money on high schools to the detriment of lower education, and if there was not enough money for both he certainly hoped it would be cut off from the top and put on at the bottom. The best education possible was none too good for mentally deficient children.

Mr. Maximilian Groszman thought that the family physician was not ordinarily in a position to detect at an early stage defects in mentality. Possibly something might be done in this direction by having competent school physicians. In his opinion, it was often most important to change the environment of the child at home, and this remark applied not only to tenement-house children, but to many reared in luxury and amid the hot-house culture and overstimulating surroundings so often found in the homes of the wealthy. In his experience many children were denounced as backward who did not at all deserve this appellation. Many were normal, but so slow that they could not keep pace with the forcing methods in vogue in our schools. About twenty per cent. of the school children had been found to be backward solely as a result of some defect of the special senses. He had been especially pleased with, and desired to emphasize, what Dr. Yale had said about children reproducing the childhood stage of their parents. Many of the so-called bright pupils were bright merely because they had a quick reaction time, and in the long race of life many of these would, like hot-house plants, never reach true maturity, while their slower classmates exhibited greater mental strength and endurance, and eventually became important members of society. The most unfortunate were not those whose mental defects any one could recognize, but those having minor mental abnormalities.

Heredity and Mental Deficiency.—Dr. T. Alexander MacNicholl said that he had been conducting an investigation into the relation of heredity and mental deficiency. Of 10,000 children, 8.8 per cent. had exhibited mental deficiency in varying degree. In 40 it was reported to be due to environment. He had been able to trace 463 children in 150 different families through three generations. Of this number, 17 were precocious in some one thing and 403 were generally deficient. There were 17 children with neurotic fathers, 78 with neurotic mothers, 265 whose grandparents had been intemperate, and 246 whose parents and grandparents had both been intemperate. Two per cent. of these children were of less than the average of intelligence. In a study of 51 strictly temperate families, having 231 children, it had been found that 3 per cent. were mentally dull.

Dr. Hermann Knapp said that nearsighted children were not usually stupid, nor were children who had been born blind, though they had no visual memory. The optic and acoustic memorizing centres were separate and distinct.

Superintendent Godwin, of the board of education, objected to the proposition to establish special or ungraded classes for those mentally deficient, for it was human nature, he said, for teachers to force out of the regular classes and into these special ones all pupils whom they did not desire to keep, whether they were mentally defective or not.

SECTION ON SURGERY.

Stated Meeting, April 8, 1901.

JOHN B. WALKER, M.D., CHAIRMAN.

Cancer of the Rectum Operated upon Eight Years Ago.—DR. JOHN F. ERDMANN presented a woman from whom he had removed an epithelioma of the rectum eight years ago. At the time of the operation in August, 1893, the patient was forty-three years of age, and there was a rather short history of rectal trouble, which had been diagnosticated as hemorrhoids. The glands had not been involved. He had cut out all but one-third of the sphincter and two inches of the rectum. There had been a marked return of the growth within three months. He had then done a vaginal amputation of the rectum. Since that operation the patient had been absolutely free from any return of the disease. At no time had there been any eversion or prolapse of the mucous membrane, and except when the movements were loose there was perfect control of the bowel.

Cancer of the Penis: Removal of Glands by Lennander's Method.—DR. VICTOR C. PEDERSEN presented a man, fifty-eight years of age, who had been operated upon by Dr. Weir at the New York Hospital fifteen months ago. In June, 1899, a small, flat sore had been noticed for the first time on the right side of the glans penis. It was very tender and would not remain healed. In September, 1899, a similar sore was found adjoining the first. He had lost fully ten pounds during this time. The growth proved to be a classical epithelioma without involvement of the glands. This clinical diagnosis had been confirmed by microscopical examination. The penis was amputated close to the body on December 9th. The iliac vessels on one side were exposed by an extension of the incision and the glands removed in this region and within the pelvis. The same operation had been done on the other side a short time afterward, and affected glands and suspicious fat and other tissue removed. In each instance the radical operation for the cure of hernia had been done. The man had been discharged from the hospital on January 28, 1901. He had gained fully twenty-five pounds in weight, could urinate without dribbling, and could copulate with fair satisfaction.

Cancer of the Rectum.—DR. JAMES P. TUTTLE read a paper on this subject, but before doing so presented several patients and demonstrated a new method of examination. The object of this method was to secure the benefit of pneumatic inflation without placing the patient in the uncomfortable knee-chest posture. The first patient presented was one who had had malignant disease of the sigmoid and upper portion of the rectum. The second case was one in which a carcinoma extending over five inches up the rectum had been removed nearly seven years ago. After the introduction of the rectal tube or speculum and a minute electric light for direct illumination, inflation was secured by a double bulb attachment to the speculum. The patient was placed in the Sims position for the examination. Another patient had had a true epithelioma of the rectum removed one year ago. The paper comprised a report of fourteen cases of carcinoma of the rectum and sigmoid that had come under his observation in the last fourteen months. There were nine sacral operations, one resection of the sigmoid flexure, and four colotomies. Of the nine sacral operations, preliminary colotomies had been made in three cases. One patient had died from shock, and one from gangrene of the sigmoid flexure. One of these cases was not a carcinoma but a melano-sarcoma. In one of the seven remaining cases there had been recurrence in seven months, and death in eleven months. So far as known, the other patients were living and well. The majority of them had lived over one year without recurrence. Two of the patients were under twenty-five years of age, the ages varying from twenty-two to sixty-six years. In one of the fatal cases death had resulted from gangrene of twelve inches of the sigmoid. This portion of the bowel had been brought down and sutured, and the post-mortem examination showed that the gangrene had resulted from an accidental division of the superior hemorrhoidal artery and the consequent loss of vitality. The speaker said that he had collected about fifteen hundred cases of carcinoma of the rectum, and the mortality had been nearly twenty per cent. almost immediately after operation. Regarding the colotomies, he said that all of the patients had died within a few months. When a patient improved very much after an artificial anus had been established, it was indicative to some degree that the carcinoma had not become general and that an operation for its removal was likely to prove successful if the patient were in a condition to stand the immediate shock of the operation.

DR. JOHN F. ERDMANN said that the majority of cases coming under his observation had been such as to require colostomy, and the results had been about as described in the paper. He had had a case of carcinoma in a person of nineteen years, and one occurring in a youth of seventeen in which the diagnosis had lain between carcinoma and sarcoma.

DR. FRED KAMMERER said that he thought it was well known that carcinoma was observed in very young people. He had personally seen four cases under twenty years of age, two in men and two in women. He had operated upon quite a number of patients in the twenties. His experience with preliminary colotomy had impressed him very favorably even in persons who might be operated upon without it. This procedure so greatly simplified the operation that, unpleasant as it was, it seemed to him good practice to do it. In two cases he had simply amputated without closing the stump. One of these he had followed, and the stump had closed perfectly and had given no trouble. He had called attention to the desirability of amputating high up, and before drawing the gut down to make sure that there was a sufficient blood supply to prevent gangrene. It seemed to him that one of the essential conditions for the successful use of the Murphy button was the coaptation of two peritoneal surfaces, yet he had understood Dr. Tuttle to say that he had brought together by means of this button a portion of bowel covered with peritoneum and another portion deprived of its peritoneal coat. He preferred suture of the intestine to the use of the Murphy button when the two peritoneal surfaces could not be brought together; indeed, he was not quite sure that Murphy had not insisted upon the necessity for having two peritoneal surfaces.

DR. GEORGE M. EDEBOHLS said that at one time he had done a few Kraske operations in women for cancer of the rectum, but had not been pleased with the ultimate results. Recently he had operated upon a carcinoma of the rectum occurring in a woman who was pregnant. The carcinoma was situated quite high up, and he had operated by removing the pregnant uterus and resecting seven inches of the bowel from above. After having cleared out the fatty tissue and glands in the hollow of the sacrum he had made an end-to-end anastomosis. The patient had made a good recovery. He was inclined to think that this method was greatly superior to the Kraske method in women, particularly because of the ease with which the fat and glands could be removed from the hollow of the sacrum.

DR. TUTTLE said he agreed with Dr. Kammerer regarding the essentials for good union with the Murphy button, but there were circumstances under which the

Murphy button was urgently needed if only to secure weak union. He never relied upon the button only, employing sutures in addition. In spite of this, every one of these cases had presented a fistula. When the carcinoma was low down, the dissection was made down to the mucous membrane of the anus, the gut invaginated, and held in this position so that the discharges would find their way externally instead of infecting the wound. One great advantage of the preliminary colotomy was that one could be sure that the bowel above had been thoroughly emptied. He did not employ the Kraske operation in any cases in which the carcinoma extended above the promontory of the sacrum. He had been afraid to undertake the abdominal operations for carcinoma of the rectum and sigmoid because statistics showed that they were attended by a mortality of about fifty per cent.

Pocket Sterilizer and Instrument Case.—Dr. W. P. Herrick presented this device. The outer case was the tray in which the instruments were placed. It was made of a size which would take standard instruments. If preferred, the instruments could be sterilized at home, wrapped up in gauze, and then transported in the metal case. The sterilizer could be placed on the market and sold at a cost not exceeding five dollars.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 13, 1901.

James Ewing, M.D., Vice-President, in the Chair.

Aneurisms of the Aorta.—Dr. O. H. Schultze presented these specimens. The first was a fusiform aneurism of the first portion of the arch of the aorta, with rupture on the right side adjacent to the right auricle and the superior vena cava. The specimen had been taken from a woman fifty years of age. There was an enormous hæmopericardium with resulting compression of the heart and death. The second specimen was a sacculated aneurism proceeding from the posterior aspect of the first portion of the arch of the aorta, and showing a marked transverse opening. It was possible that trauma might have been the cause. In both cases there had been no positive evidence of syphilis. The first case showed marked arteriosclerosis of the abdominal aorta and a beginning aneurism at the cœliac axis. There was also a chronic interstitial nephritis. In the second case there had been only a general passive hyperæmia of all the organs. The patient was a man aged thirty-five years. This aneurism had ruptured adjacent to the right auricle and superior vena cava. In that case also the immediate cause of death had been the pressure exerted by the blood which had accumulated in the pericardium. In both cases death had occurred suddenly and no clinical history had been obtainable. The speaker thought that the old notion about arteriosclerosis being the all-sufficient cause of aneurism had been exploded.

Dr. L. T. Le Wald referred to a case of aneurism that had ruptured while the patient was engaged in the act of defecation. The rupture had occurred in the last portion of the thoracic aorta and in close relation to the diaphragm. In that case there had been a distinct arteriosclerosis and a history of syphilis.

Dr. Harlow Brooks said that he had presented three years ago three cases of small sacculated aneurisms of the ascending arch very similar to the second case presented by Dr. Schultze. In these he had studied carefully the histology of the aneurismal sac and of the walls of the aorta. The arteriosclerosis of the general arteries in these cases had not been great, but had been of a patchy character, and the bases of the aneurisms had been chiefly involved. In those cases the arteriosclerosis had apparently been the cause of the aneurism. All of the subjects in this series were young.

Dr. Schultze said that the statement that one of the aneurisms was probably of traumatic origin had been based on the fact that the longer diameter of the opening, which was oval, was almost strictly in the transverse axis of the aorta. By the term "trauma" it was not meant that any direct force had been exerted from without, but rather that work involving considerate physical exertion might have subjected the arch of the aorta to pretty severe pressure. If a tear occurred under these circumstances it was more apt to be in the transverse diameter. Although much arteriosclerosis was frequently seen with aneurisms, it was also true that a very excessive degree of arteriosclerosis was often observed without the occurrence of aneurism. Dr. I. Adler had recently raised the question as to the rôle played by the yellow elastic fibre in the aorta in connection with the formation of aneurisms. It was known that vesicular emphysema was hereditary, apparently as a result of the quality or congenital weakness of the yellow elastic fibre, and it seemed not improbable that a similar relation might exist between this fibre and the development of aneurisms.

A Case of Primary Carcinoma of the Liver.—Dr. A. E. Thayer presented a specimen of carcinoma of the liver taken from a woman about forty-five years of age. She had entered a hospital about two weeks before death, complaining of some abdominal distress, and examination had shown marked ascites. She had been tapped and about fourteen quarts of blood-stained serum removed. Through the puncture there had been discharged considerable fluid—a quantity estimated to be as much as that removed by the tapping—but this latter fluid had not been blood-stained. The woman was obese and not particularly anæmic. There was slight jaundice of the conjunctiva and in patches over the abdomen. On autopsy, about 1,500 c.c. of clear serum had been found in the peritoneal cavity. There was a broad band of small varicose veins along the reflection of visceral to the parietal peritoneum. The liver was not especially enlarged. In the right lobe was a well-marked cirrhosis and comparatively little involvement by the tumor. The left lobe was for the most part replaced by nodules of neoplasm. The round ligament was enormously increased by fat and connective tissue, and on each side were prominent varicosities. With the exception of its shrunken condition the stomach was normal. There was no neoplasm in the duodenum. Microscopical sections of the pancreas had shown no distinct evidence of carcinoma. A careful search showed that the stomach, liver, pancreas, intestine, and the adrenals were not affected by the neoplasm, and he felt that this tumor was primary. The larger masses were of a mottled red color, and on being scraped yielded very little cancer juice. On section through the liver, a large mass was found near the hilus. It was generally yellow in color, but contained a thrombosed portal vein. Another such mass was also found in the hepatic vein. The speaker thought there had been first a cirrhosis of the hæmatogenous variety, and that from the newly proliferated bile ducts the neoplasm had formed, and had through the portal vein given rise to the very rapid metastasis. Sections were exhibited under the microscope.

Dr. Schultze said that the invasion of the portal vein was a very interesting feature, and probably explained the rapid extension of the growth, particularly into the left lobe. The question might arise as to whether the growth had started directly in the hilus or had originated in the pancreas or somewhere else in the vicinity. There might certainly be a transition between the ordinary proliferation of the bile ducts in cirrhosis of the liver and primary adenocarcinoma.

Dr. James Ewing said that well-authenticated cases of primary carcinoma of the liver were so few that it seemed wise to take extraordinary precautions to make sure of this diagnosis before it was placed on record. This specimen showed a totally different arrangement from the usual form of hepatic carcinoma. It might belong to the cells of the gall duct or the pancreas, probably the latter, and after a close study of the tumor he did not feel that the question had been fully decided. A very exhaustive examination of the pancreas would be required.

Blood Slides from a Case of Lymphatic Leukæmia.—Dr. T. C. Janeway said that this case was interesting as showing that a sharp line could not be drawn between acute and chronic lymphatic leukæmia. The subject of this report was a boy of six years. The trouble had begun three months previously with a swelling over the masseter muscle, and one month later the glands of the neck had become enlarged. The boy had then developed a marked pallor. Other glands became palpable, but no mediastinal glands were thought to be enlarged. There had been no hemorrhages, and there was no leukæmic retinitis. The blood examination showed 40 per cent. of hæmoglobin with a full number of cells. There were 219,000 white cells, of which 98 per cent. were lymphocytes, and of the latter nearly 87 were large. The red cells were moderately pale. The result of this examination pointed to a typical acute leukæmia, yet the boy presented clinically a moderately progressive leukæmia. Cases of this kind compared with cases of chronic leukæmia of long duration seemed to show that it was impossible to classify acute lymphatic leukæmia as a separate disease. Specimens were presented under the microscope.

Dr. Ewing said that even Fraenkel's own countrymen had not accepted his claims regarding the significance of large lymphocytes in leukæmia. Fraenkel had stated that acute leukæmia was always lymphatic, and when acute was always characterized by the presence of large lymphocytes. Rosenfeld had recently claimed that when lymphatic leukæmia affected the lymph nodes and the spleen, and other lymphatic structures excepting the marrow, it was chronic in course and was marked by the presence of an excess of small lymphocytes; and that when it attacked the marrow exclusively or chiefly its course was acute, and was marked by severe anæmia and an excess of large lymphocytes.

Dr. T. C. Janeway said that he had seen a few years ago a case of lymphatic leukæmia which had run eighteen months with enormous enlargement of the superficial glands, and yet the blood examination had shown a goodly proportion of large lymphocytes. He had seen eight cases of lymphatic leukæmia in the last few years, and they had presented every possible variety of blood picture.

Dr. H. J. Boldt presented several specimens.

Tuberculosis of the Kidney, Ureter, and Bladder.—The first specimen showed tuberculosis of the kidney, ureter, and bladder. The tuberculosis had been diagnosed prior to death during the examination for the pelvic ailment of which the patient complained. Suspicion had been aroused by the vesical symptoms and the thickening of the right ureter detected by bimanual palpation. It had been thought best first to operate for the pelvic disease, a suppurating ovary, and later to attack the renal and ureteral disease. Unfortunately the slipping of the ligature a few hours after the operation caused a fatal intraperitoneal hemorrhage. The interesting feature was the possibility in some instances of attention being directed to serious ureteral disease by a bimanual examination.

Carcinoma of the Cervix Uteri; Removal by the Cautery.—This case was reported to show the advantages of removal of the carcinomatous uterus with the aid of the galvano-cautery. The disease had begun in the cervix and unfortunately had advanced to such an extent that the result of radical operation seemed hopeless. From the observation of other patients operated upon by him with the galvano-cautery, and the results achieved by Byrne, of Brooklyn, Mackenrodt, of Berlin, and others, he had been induced to attempt it in the present case. The operation had been done only yesterday. The advantage of extirpation with the heated knife was that the destruction of epithelial elements extended some distance beyond the line of cutting, but there was a disadvantage from the same source, *i.e.*, secondary breaking down from a burn or slough of other structures. This had happened to him in one instance. In that instance the ureters had given way several days after operation, yet in spite of this accident the patient had remained free from recurrence for four years and was still well and enjoying good health. The ureteral lesions had been subsequently attended to by a colleague. The time consumed and the tediousness of this method of operation should not cause any hesitation in its adoption if it should be shown that the ultimate result was greater freedom from recurrence.

Chronic Metritis and Suppurative Salpingitis and Ovaritis; Vaginal Ablation of Pelvic Organs.—The uterus, tubes, and ovaries from this case were exhibited. The patient, a woman aged thirty-six years, had been infected with gonorrhœa about two months after the puerperium, and had had numerous attacks of pelvic peritonitis. She suffered almost constant pain in the abdomen, and menstruated at intervals of two or three weeks. He had operated in October, 1900, and since the beginning of the present year she had been perfectly well.

Gonorrhœal Salpingitis; Removal of Uterus, Tubes, and Ovaries by Vaginal Hystero-Salpingo-Oöphorectomy.—The patient, a multipara of thirty years, had been infected with gonorrhœa soon after marriage. He had attended her in five attacks of intense pelvic peritonitis, and she had had several others. She had been practically well since the performance of the radical operation last November. At the operation it had been necessary, because of the extensive adhesions involving the adnexa, to bisect the uterus before its removal. The specimens presented showed the lesions in a characteristic manner.

The Bacteriology of Lobular Pneumonia.—Dr. George Blumer, of Albany, read this paper. He said that in looking over a series of 350 autopsy records, most of them in connection with institutions having an acute service, he had been impressed with the large proportion of cases of lobular pneumonia. In the 350 autopsies bronchopneumonia was present in 114 cases, or 32.5 per cent. In this group were but 15 cases of acute lobar pneumonia, or 4.2 per cent. A table covering 168 cases of lobular pneumonia in the adult was quoted from. There were 131 simple infections, or 78 per cent., and 37 of mixed infection, or 22 per cent. The pneumococcus of Fraenkel had been found in 39 per cent., streptococci in 16 per cent., staphylococci in 10 per cent., the bacillus of Friedländer in 9.5 per cent., and the colon bacillus in 7.7 per cent. In his own cases the cultures had been taken from the lung at autopsy by burning the area with a red-hot knife. The cultures had been made on agar or blood-serum slants, and the organisms studied in various culture media. The diagnosis of lobular pneumonia had been confirmed in every case by microscopical examination. Of the cases of lobular pneumonia, 53 had been in adults, and 20 had been mixed infections. Of a series of 77 cases in children, there had been 57 single and 43 mixed infections. Pneumococci had been found in 61 per cent., streptococci in 33 per cent., staphylococci

in 32 per cent., the Friedländer bacillus in 14 per cent., and the colon bacillus in 26 per cent. In his own cases the pneumococcus had been a rather rare organism, as had also been the Friedländer bacillus, whereas the pyocyaneus and the proteus vulgaris had been relatively common. The colon bacillus had been present in a rather large percentage of cases. The author ventured the suggestion that there might be a geographical distribution of bacteria. The great infrequency of true lobar pneumonia would suggest that perhaps pneumococcus infections were uncommon in Albany. The death rate from pneumonia in certain months was found to be three times higher in New York City than in Albany. Practitioners of the latter city stated that it was relatively uncommon to see a frank case of typical lobar pneumonia. The frequency of the colon bacillus was probably explicable on the ground of post-mortem invasion. It was probable that, in some cases in which the colon bacillus only was found, it had displaced the pneumococcus. The majority of the writers on the bacteriology of normal lungs inclined to the belief that during life they were sterile, but some believed that bacteria were commonly present in the normal lung. Of 20 lungs examined by him which were acutely congested, 6 were sterile. Of the others, aureus was present in 3, albus in 1, Friedländer's bacillus in 1, and there were one or two mixed infections. In all but 6 of the 18 cases there was a general infection as well as a pulmonary infection. Of 6 cases of chronic passive congestion examined, all were sterile—a rather interesting circumstance, taken in connection with the well-known fact that such lungs resisted tuberculous infection well. In the 4 cases of pulmonary œdema examined, all contained bacteria. Of 17 lungs which were both congested and œdematous, only 2 were sterile. Of the 15 cases in which bacteria were present, only 6 were cases of pulmonary without general infection. Four normal lungs were examined, and all contained bacteria. In all of the cases in which the colon bacillus was found there had been a general invasion. In some of the cases described, definite foci of infection were present in other parts of the body than the lungs. Many of the cases of lobular pneumonia were associated with general infection. Pearce had stated that when both general and local infection existed, the same organism was found in both, and this had been in general the experience of Dr. Blumer. In the mixed infections in which there was both general and local infection, both organisms were sometimes generally distributed, but in some instances only one of the organisms was generally distributed. From a histological standpoint the exudate of lobular pneumonia could not be differentiated from true lobar pneumonia in a great many cases. Eight cases of bronchopneumonia in adults complicating typhoid fever had been studied. The streptococcus had been present in 2, the colon bacillus in 4, the pyocyaneus in 1. The relation of bronchopneumonia to chronic nephritis was studied in 10 cases, the colon bacillus being found in 6 and the streptococcus in 2. A general infection was found in 7. In 6 cases of lobular pneumonia with arteriosclerosis the colon bacillus was found 4 times, the streptococcus and proteus each once. The cases studied seemed to show that in merely congested and œdematous lungs, as with bronchopneumonia, a general infection was frequently present. The lungs were probably much more frequently the portal of infection in general infections than was commonly supposed, and often without marked pulmonary lesions.

Dr. A. J. Lartigau said that he had been particularly interested in the geographical distribution of micro-organisms to which allusion had been made in the paper. Having worked in both Albany and New York City, he had had an opportunity to judge of this matter. The pyocyaneus infections were certainly very common in Albany, while very uncommon in New York City. He had found bronchopneumonia very common in autopsy work in Albany, whereas in New York City lobar pneumonia was the rule. The majority of investigators had found the pneumococcus with far greater frequency than had Dr. Blumer. If more complete bacteriological methods had been practicable, it was quite probable that more pneumococcus infections would have been discovered. A great variety of culture media had been found requisite in such investigations. He personally believed that the pneumococcus would be found with increasing frequency as the technique was perfected. He had been recently investigating the question of the presence of micro-organisms in the normal lungs of rabbits. These lungs had been found sterile, as a rule, though he had occasionally found pneumococci and the colon bacillus.

Dr. Martha Wollstein said that she had been especially interested in the bacteriology of pneumonia in infants. At one time she had examined bacteriologically one hundred bronchopneumonias of infants. They had been divided into primary and secondary cases. The primary had shown the pneumococcus present in more than seventy-five per cent.; the secondary cases in a very much smaller percentage. The pyocyaneus had been found three times in the secondary cases. It had been found better to avoid the use of hot knives (or to burn the surface of the organs), but to sterilize the knives in metal boxes, and to use them at the autopsy perfectly cool. It was extremely rare to find a perfectly healthy lung in an infant at autopsy, but in a few instances such lungs had been met with, and had been found sterile.

Dr. C. H. Norris said that he had found it very difficult in many instances to differentiate between streptococci and pneumococci, and this had led to much confusion. Much stress had been laid upon the different characteristics afforded by the growth in broth.

Dr. Ewing commented upon the use of the terms lobular and bronchopneumonia as synonymous, and called attention to the fact that some pathologists believed that a distinction should be made between them. His impression was that Dr. Blumer had included both simple exudative lobular pneumonias and the other type of circumscribed pneumonias. He had been struck with the conclusion of the author that the lungs often served as a port of entry for germs in terminal septicæmias.

Dr. Blumer said that many writers on this subject had made use of only one culture medium. He had been interested in the point made by Dr. Wollstein regarding the possible destruction of some of the pneumococci by the use of hot knives. His paper included both lobular and bronchopneumonia, though he believed with Dr. Ewing that there was a distinction between these two forms. He had used these terms interchangeably because most of the cases hitherto reported had included both varieties.

A vote of thanks was then tendered Dr. Blumer for his instructive communication.

Blennorrhagic Arthritis with fluid about the joint is best treated by rest in bed, compression by means of flannel bands, derivatives such as tincture of iodine, and vesicants. When the fluid is abundant and does not diminish under compression, a puncture should be made with the trocar and 8 c.c. of a solution of phenic acid (five per cent.) injected. When the hip joint is affected continual extension with a weight gives good results.—Hurtado.

MANHATTAN DERMATOLOGICAL SOCIETY.

Stated Meeting, April 5, 1901.

WILLIAM S. GOTTHEIL, M.D., CHAIRMAN.

Pityriasis Rosea.—DR. J. SOBEL presented two cases of pityriasis maculata et circinata in children aged eight and twelve years respectively. The latter bore some resemblance to seborrhœal eczema. The face was involved in both, a not uncommon occurrence. Areas of this disease when painted with Lugol's solution appeared of a deep mahogany or dark-brown color (Allen's test). This condition was often diagnosticated as syphilis.

DR. LUDWIG WEISS stated that if one scratched an erythematous patch it became scaly. This sign he considered almost pathognomonic. Differentiation must be made from seborrhœal eczema and psoriasis. He preferred the name pityriasis maculosus tonsurans.

DR. GOTTHEIL considered both classical cases. Rosea was a name which meant very little.

DR. BLEIMAN remarked that some early cases of psoriasis guttata were difficult to differentiate.

Phototherapeutic Apparatus.—DR. GOTTHEIL presented an elaborate apparatus for the Finsen treatment of various dermatological affections.

Lupus Vulgaris.—DR. GEYSER exhibited a patient with an extensive lupus vulgaris of the face, which had been successfully treated with the *x*-ray. The right side at present showed a large, smooth, shining cicatrix and a few linear masses: the left side showed a superficial burn and a mild degree of alopecia due to the rays. Each séance lasted from seven to ten minutes and was followed by a static spray for the relief of pain. This method was superior to Finsen's because exposure was shorter and the penetrating power was greater.

Chancre of the Labium in a Girl of Fourteen.—DR. MARTUS presented this patient, who had a generalized papulo-squamous-pustular syphiloderm. Sexual contact was admitted. Adenopathy, iritis, and mucous patches were present. The case had been diagnosticated as seborrhœal eczema by a general practitioner.

Multiple Molluscum Fibrosum.—DR. LUDWIG WEISS presented a woman with multiple mollusca showing the development of the disease. Many lesions were more apparent to the touch than to the sight; some were sessile, some pedunculated, and others were soft.

DR. GOTTHEIL said that such cases were rare. The softness in some led him to think of an angiomatous element.

DR. OCHS stated that such cases responded at times to Asiatic pills.

Nævus Unius Lateris.—DR. GOTTHEIL presented this case for opinions as to diagnosis. In a boy aged ten years there was a congenital growth under the right arm pit, which consisted of tuberous excrescences, very dark in color in most places, pinkish in others. There were a few isolated patches to the outside and on the inner side of the forearm a row of similar though lighter lesions.

DR. L. WEISS considered the condition a very rare one—acanthosis nigricans. The region of the axilla was characteristic.

DR. J. SOBEL said that this case was similar to those described by Dr. Prince Morrow of this city under the title of linear nævus. He would call this particular case nævus linearis verrucosus. The lesions on the inner side of the forearm scattered along the course of the cutaneous nerves corroborated the diagnosis.

DR. GOTTHEIL said the growth did not correspond to acanthosis nigricans. He would call it nævus unius lateris or nævus papillomatosus. The growth would shortly be removed by Dr. A. E. Isaacs, of Beth Israel Hospital.

Sarcoma Cutis.—DR. GOTTHEIL presented one positive and one probable case. The former was corroborated by microscopical examination. The second was either disseminated sarcoma or syphilis.

DR. LUDWIG WEISS stated that the diagnosis in the second case rested between sarcoma and lymphangioma tuberosa multiplex.

Chrysarobin Dermatitis.—DR. SOBEL presented this patient. The condition followed the use of a five-per-cent. ointment for psoriasis. He preferred traumaticin or collodion as a vehicle for this drug.

Gumma of the Sterno-Cleido-Mastoid and Clavicle.—DR. GOTTHEIL presented this patient.

DR. SOBEL said there were two distinct masses. The region of the sterno-clavicular articulation was more or less characteristic for gummatous deposits.

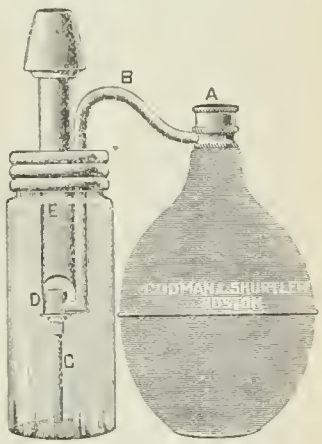
New Instruments.

AN EASY-WORKING, NON-SPILLING ATOMIZER.

BY EMMET L. SMITH, M.D.,

CHICAGO, ILL.

THE instrument herewith illustrated has been devised in order that the patient may have an atomizer that can be depended upon for instant use at any time—strong in construction, simple in mechanism so as not to get out of order. These points are necessary when an instrument of this kind is used by all classes of people. If it is out of order when they are expected to use it, they omit its use. If it is knocked over in its usual place, they pick it up and expect it to work without delay; and if it does not work, their exclamations generally include the doctor who ordered it as well as the atomizer.



The bottle is of heavy glass, and the metal parts are made strong enough to hold their shape.

The air is forced through the heavy tube *B* into an air chamber *D*, which surrounds the small point of the supply tube *C*. If this opening around the point of the supply tube is large enough (as in the case when hydrocarbon oil is used), the instrument will atomize very easily; the compression of one finger on the bulb will produce a spray. The fluid is drawn up and atomized at the point *D* and carried through the tube *E* into the nasal cavities. As the point of atomization is at *D*, it is easily seen that it cannot do any injury to the mucous membrane. This is quite in contrast to the instruments that have the atomizing-point placed within the nasal cavities.

Another important feature is that, when the atomizer is ready for use, the only way the solution can get out is through the tube *E*, and therefore the bottle can be one-third full and can be held in any position without spilling.

This atomizer is compact, and can be carried in the pocket or satchel, laid under the pillow at night without danger of spilling, and is always ready for instant use.

Thanks are due Messrs. Codman & Shurtleff, of Boston, for their painstaking care in the construction.

Surgical Suggestions.

Retroplacental Hæmatoma is much smaller when the hand is kept on the uterus. Little anxiety should be entertained about leaving portions of the membranes behind.—HEARD.

Appendicitis.—The same judgment which we exercise in ordinary business affairs, if applied to a diseased appendix, would suggest its removal at the earliest moment compatible with proper preparation.—J. L. WIGGINS, *St. Louis Medical Review*, January 19th.

Prostatic Hypertrophy.—Total resection of the spermatic cords produces less traumatism and danger to the kidneys than castration and vasectomy. We avoid the psychic disturbance incident to removal of the testes and the latter shrink so gradually that there is little complaint.—G. FRANK LYDSTON.

Cancer of Uterus.—I regret that some surgeons still cling to amputation of the cervix for cancer of that portion of the uterus. It is not so encouraging or reasonable as attempts at making an ocean from separate rain drops. It has done much toward generating opposition to surgical treatment of this disease.—W. BOVÉE.

A Truly Great Surgeon should perform all his work in a really artistic manner; a little experience will soon convince you that the cleanness with which an incision is made, and the accuracy with which the margins are subsequently coapted, has an influence on the rapidity of union and on the final result.—PARSONS.

If the Gall Bladder is so seriously diseased as to warrant a surgical operation for its relief, it is better practice to remove it *in toto* than to leave it as a place for the further accumulation of gall stones, or as a point for the setting up of new inflammations.—C. CUSHING.

Gonorrhœal Peritonitis.—There is reason to believe that gonorrhœal infection of the peritoneum does not always go on to suppuration. Sealed tubes and damaged ovaries may produce sterility. There is marked tendency to recurrence. The second attack is likely to be more severe. The gonococcus lies dormant and then breaks out with renewed activity.—F. W. EDEN, *Clinical Journal*, February 13th.

Brain Tumor.—While a comparatively small growth may produce the classical group of symptoms which enable us to locate accurately and remove successfully, yet a surprisingly large growth may develop also in the motor cortex with a group of manifestations so foreign to what we would expect as to mislead even the wary and painstaking examiner.—A. W. DUNNING, *Northwestern Lancet*, January 15th.

In Plague Buboes, blister the skin with liquor epispasticus, and as soon as the blister has risen, poultice with linseed meal every four hours to promote suppuration. Buboes make their appearance, as a rule, on the second or third day of the attack, but may appear even before the temperature rises. They vary greatly in size and position. Sinuses sometimes form, in spite of all precautions. These should also be opened freely. No case of ulceration or sloughing of any large vessel has come to my notice in connection with plague buboes, although large arteries have been frequently exposed; but great œdema of the surrounding tissues has necessitated incisions in the neck and the scrotum, to prevent gangrene and injurious pressure effects.—R. W. H. JACKSON.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 20, 1901:

	Cases.	Deaths.
Tuberculosis	248	185
Typhoid fever	22	13
Scarlet fever	729	37
Measles	280	10
Diphtheria and croup	272	45
Smallpox	38	10
Varicella	43	0
Cerebro-spinal meningitis	0	4

Peroxide of Hydrogen merits an important place in therapeutics, as it is non-toxic, inodorous, a powerful deodorizer, a valuable antiseptic, and a hæmostatic of the first order.—MARCEL RIFAUX.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 20, 1901:

		Cases.	Deaths.

THE OPERATION FOR RADICAL CURE OF INGUINAL HERNIA, AT THE END OF THE CENTURY, AS I SAW IT PERFORMED BY BASSINI, LUCAS-CHAMPIONNIÈRE, DE GARMO, COLEY, AND BROCA.

By CAMPBELL FORD, M.D.,

SAN FRANCISCO, CAL.

Dr. Bassini is professor of surgery at the University of Padua, or correctly Padova, which is situated on the historical Venetian plain, a short ride on the cars from Venice. The city is now reduced to almost a village in size, though its gates and walls, buildings and canals speak of the time when it presumed to rival Venice, and Venice was the envy of the world. The University was the most famous one of the Middle Ages. There Dante, Petrarch, and Tasso were students and Galileo spent a portion of the time of his exile in teaching, for, though the laws were severe and were executed with a rigor unknown before or since, there was perfect freedom of speech. It was said at one time to have had more than fourteen thousand students. Although the other departments have taken part in the general decadence, the medical faculty is still one of the best in Italy, a large part of its prestige being due to Professor Bassini.

I called upon him for the first time Thursday, July 12, 1900, and was requested to return the following Saturday at 5 A.M., when I might witness him perform three of his operations for hernia. I returned on Saturday and found two more cases had arrived, making five in all, three single and one double.

Professor Bassini is a dignified, courteous gentleman, apparently about fifty-five years of age, of medium height, with a very erect, bony, and muscular frame. He has a steady eye, full head of hair, and a wavy Van Dyke beard, and is modish in dress. He speaks German, I am told, very well; but English he speaks slowly and with difficulty, and inaccurately. The most of our conversation was in French. He very kindly commented upon every step of his operation. If anything displeased him he became very much excited, and tapped the assistants' hands and commended the nurse in particular terms, neither of whom replied or paid the slightest attention.

The building was one of the kind common there, with the operating-room made apparently from a bedroom. There was a complete absence of operating-room paraphernalia; a sterilizer and two small tables covered with bichloride cloth and a plain table much like our old dissecting-tables comprised all the furniture. The light was good. Very little preliminary treatment was given the patient, a physic being about all. An enema was given about four o'clock the next morning if necessary. The night before the operation the site, the legs, and the body to the armpits were thoroughly scrubbed with soap, salt solution, and 1 : 1,000 bichloride. This was repeated by Bassini himself just before the operation, the operator and the assistants sterilizing their hands at the same time. Two small tables were placed on the side where the professor stood. On one was a tray with a few artery forceps, a couple of scalpels, a pair of scissors, and two retractors; also a dish containing silk ligatures. On the other were a brass sterilizer containing sterilized cheesecloth, rubber cloths, and absorbent cotton, and also a large bowl or two containing 1 : 1,000 bichloride and one containing salt solution. The patient was placed on the table, his legs were covered with rubber cloth, his knees strapped down, and sterilized rubber was placed above and below the site of the operation, which, with all the adjacent parts, was covered with 1 : 1,000 bichloride cheesecloth. From the sterilizer a piece of cheesecloth was picked up by Bassini, it all having been cut into yard squares. He took hold of two corners and his assistant of the other two, and they folded and refolded it until it was about four inches wide; then it was cut into squares for sponges. This odd manœuvre, always done in perfect silence, and high over the patient's body, was never omitted. An assistant, one female nurse, and the anæsthetist comprised the staff. Chloroform was given in large quantities by the open method. The nurse assisted the anæsthetizer. When the patient was fully anæsthetized, the cheesecloth was slit with a pair of scissors and the skin exposed. The assistant picked up the skin between his left thumb and forefinger, while the professor took hold of the same fold in the same manner, and with his scalpel cut it, and, before either loosened their grasp, caught all the vessels. When the skin was released, the cut extended from about the level of the spine of the ilium down to near the pubes, and in depth to the external oblique. The larger the hernia, the shorter was the skin incision. With a pair of scissors the external oblique was slit up beyond the internal ring, then dissected internally to the rectus muscle and downward to the shelving edge of Poupart's ligament. The cord and sac were then picked up, and their separation with the fingers was commenced at a point usually in the side of the sac. When it was well exposed it was first nicked and then freely opened, the inside inspected, and the lines leading to the bladder were pointed out. Thickened, diseased, adhered, or presenting omentum was drawn down, ligated with silk in small sections, and excised; in one case more than a double handful was removed. The entire canal was then with a scalpel thoroughly cleared of all fat, fascia, etc.; the sac was clamped, tied off with silk high up, and the stump dropped. The vessels of the cord were not touched, though small nodules of fat were picked off. A ligature was then passed under the cord and anchored to the cheesecloth with a pair of forceps so as to pull it out of the way. No hook was used as is ordinarily figured in American and German text-books.

The assistant retracted the edges, exposing the rectus muscle and the shelving edge of Poupart's ligament. Then with a full curved dragon-eyed needle, held with forceps, a lap-stitch was taken, commencing well in the rectus and including the internal oblique, transversalis muscle, and fascia, and emerging well back of the edge of the muscle. The finger was used to guide the point of the needle, then the needle was passed through the shelving edge of Poupart's ligament. The first stitch always, and the second stitch sometimes,

included a part of the rectus muscle. From four to six of these single stitches were used, approaching the upper angle of the internal ring. After their insertion, commencing at the upper one and carefully determining the constriction of the cord, they were tied and the ends cut short. The cord was then dropped, and with the needle without forceps a continuous stitch was used to suture the external oblique and the external ring. The size of the external ring was always carefully estimated by both Bassini and the assistant. When it appeared too large a few stitches very close together were inserted. The skin was then sutured with the double-knot stitch or friction-knot stitch, which I had the honor first to describe. And while I was pleased I was not surprised, as I had sent Professor Bassini, Professor Kocher, of Berne, and Dr. MacCready, of London, reprints of them in 1896. Professor Kocher and Dr. MacCready both replied, Dr. MacCready saying he purposed trying them at once. The wound was dressed with sterilized gauze, covered generously with cotton. The patient was drawn down to the foot of the table by the nurse, who stood between his legs and placed an iron bar lengthwise under each

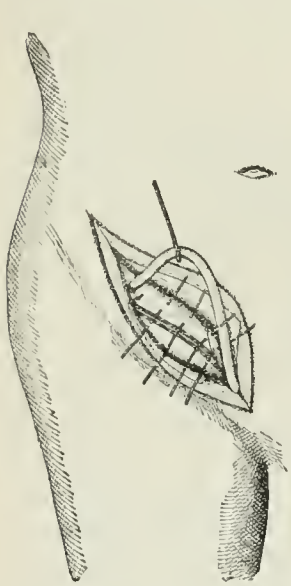

FIG. 1.—First Step in constructing the Canal: showing Bassini's lap stitches, one tied and the other placed.

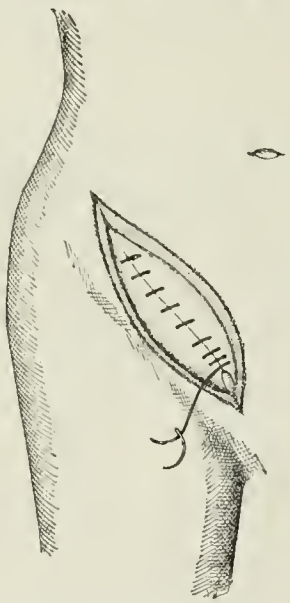

FIG. 2.—Second Step: showing Bassini's method of closing the external oblique over the cord with the continuous stitch.

one, crossing them under the buttock, with which he elevated the patient while the professor applied a plaster-of-Paris spica bandage. The time of the operation varied from thirty to forty-five minutes.

Professor Bassini informed me that he had performed nine hundred operations after the above method, and had not since done any operation after the method described by him about ten years ago, when he reported two hundred and sixty-two cases, and which is the one known and described in this country and in Germany. His recurrences with his later method he estimates to be less than four per cent., many of which are due to wasting diseases.

Dr. Lucas-Championnière, surgeon to the Hospital Beaujon, and to the celebrated Hôtel Dieu in Paris, is the antithesis of Bassini in his surroundings, dress, work, physique—in a word, everything. He is a small man with a long, large head, which makes his appearance more like that of a Scotchman than of a Frenchman; and in fact he was a student in Scotland, in the early sixties I believe. He speaks English well, and his clinic is a favorite of Americans and English. He informed me that up to that time he had operated upon nine hundred and sixty cases of inguinal hernia.

I spent some months in Paris and observed many of his operations for hernia as well as others in the whole range of surgery. His operating-room at the Hôtel Dieu is of the pre-germ-theory origin, and while not ancient nothing I saw was suggestive of anything later than mediæval origin. For the operation the patients are prepared by the usual scrubbings, antiseptics, etc. The doctor washes his hands with soap and then dips them into hot carbolic-acid solution of from two and one-half to five per cent. strength. The incision is made on the usual line over the internal ring, and with the greatest rapidity, ease, and precision by free strokes of the knife the cut is carried down to the internal ring. The sac is freed and, holding it up with his sac forceps, it is ligated and cut off; then with his forefinger the stump is carried up along Poupart's ligament, and with a Reverdin needle two stitches are passed under it, including the muscles and ligament, and tied, firmly anchoring it well away from the upper angle of the ring.

If the patient is of full habit, he is allowed to bleed freely, with the idea of preventing fever. Using the heaviest catgut prepared after one of the earliest formulas of Lister, and with a Reverdin needle, he inserts the sutures which he terms U-sutures, and which Halsted calls mattress sutures, and which are in fact interrupted sutures put in sidewise. Two rows are put in through all the muscles and fascia *en masse* of the abdomen on the upper side, and Poupart's ligament on the lower. One row commences back about an inch from the edge of one flap, and then passes through the other flap very close to the edge. The second one commences close to the edge of the first flap, and passes to the same distance back on the second as the first row did on the first. After they are all placed they are tied, forming a large, thick lap-joint. The muscles overlap the ligament usually, although by no means always. Before closing the skin the wound is sponged out with a five-per-cent. solution of carbolic acid in water. Interrupted sutures are used to close the skin. A rubber drainage tube is inserted with the free end at the iliac end of the cut. A dressing of antiseptic gauze, covered with a kind of peat instead of absorbent cotton, is held in place by a spica bandage. All visitors are allowed to approach the operating-table in their street clothes. The forbidden zone is the wound. This is touched only by the doctor, and sometimes, though rarely, by his assistants. Only about five per cent. suppurate, and many of these only after the second dressing, which is done by the internes. This is certainly a splendid showing under such adverse circumstances, for the doctor cannot be blamed for the manner in which the municipality of Paris furnishes its hospitals.

Professor De Garmo, of the Post-Graduate Hospital and Medical College of New York, is the only surgeon whose practice is now entirely limited to hernia and its complications. He is an avowed advocate of the Bassini procedure, and has performed that operation on adults more times than any other person except Bassini himself. In seven hundred and forty operations he has used the Bassini method six hundred and twelve times with only eight recurrences. Dr. De Garmo's personality is well known to the profession, and his authority is practically undisputed. He performs a rigidly aseptic operation, and like Bassini almost entirely without assistance.

He is somewhat neater and faster in his work, taking from ten to fifteen minutes less time than Bassini, and has performed it in ten minutes. The external cut is made on the flat, just over the internal ring, and is scarcely half as long as Bassini usually makes. In one case I saw it appeared to be no more than two inches. Hæmostasis is very carefully done, by the use of the ordinary gauze sponge and the ligature of all the vessels with plain catgut. The external oblique is slit

up to a point above the internal ring; the cord and sac are then picked up *en masse*, and their separation is commenced usually on the side of the sac. After the sac is well freed it is carefully opened and its inside inspected. All diseased or adherent omentum is drawn down and tied off in sections with catgut. He holds up the sac and carefully protects the viscera internally and the elements of the cord externally while his assistant ligates it. The sac is then cut and the stump dropped. Pronounced varicosities of the veins of the cord are unhesitatingly excised. He rather prefers some constriction and compression of the veins than their total obliteration. The wound is thoroughly cleared, all hemorrhage and oozing being perfectly controlled, and the reconstruction of the new canal commenced. The cord is lifted up and held out of the way with the hands. With a blunt, full-curved needle designed by himself, threaded with chromicized kangaroo tendon, a stitch is taken including the internal oblique, transversalis, and transversalis fascia. It passes through the shelving edge of Poupart's ligament, and without cutting of the thread a square knot is tied and the single-knot stitch described by me inserted through the entire line, and frequently, still without cutting it (the thread), the external oblique and the pillars of the ring are sutured together with the same stitch. In this line of sutures a wide insertion is taken, causing a considerable surface of approximation.

The first stitch embraces the cord very snugly, in fact it appeared to me to be constricted to about two-thirds of its normal size. A moderate amount of primary swelling of the testicle is not objected to. The skin is closed with the subcuticular stitch, using medium-sized, plain sterilized catgut. The wound is sealed with collodion and a light dressing applied.

The other famous operators in this branch of surgery whom I have had the pleasure of observing were Coley, of New York, and Broca, of Paris. Dr. Coley is so well known as the author in conjunction with Dr. Bull of almost all of the text-books on this branch that no extended description is necessary. He performs the Bassini operation. The sac is dissected until it widens out into the peritoneal cavity; then holding it up and watching, he transfixes it with a sharp, curved needle threaded with catgut. It is then tied and the stump dropped. The cord is transplanted in the usual manner. With this exception in suturing the deep muscles to the shelving edge of Poupart's ligament, the first stitch is taken above the cord. The external oblique is closed with a kangaroo tendon by a continuous stitch. In this row he informed me that after some practice he purposes to use a single-knot stitch. He invariably wears finger cots, and the assistants and nurses wear rubber gloves. The last operation I saw him perform was on a girl about eleven years old, and was without apparent hurry finished in eleven minutes.

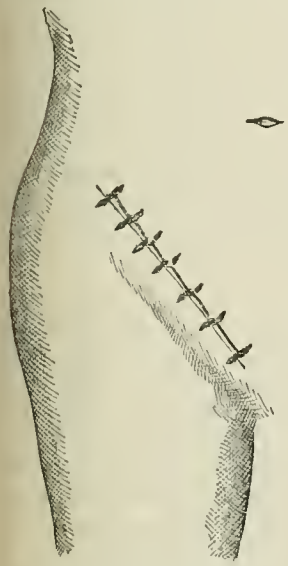

Fig. 3.—Third Step: Bassini's closure of skin with the Ford double-knot stitch.

Dr. Broca is a general surgeon, and has performed a large number of operations on the mastoid cells. The most striking points to me were his perfect *sang froid*, and rapid and free incisions. In his hernia operations he sutures up the canal with a Reverdin needle. Usually the suturing and dressing are turned over to an assistant.

The innovation of Bassini in using a lap stitch is, I think, a valuable one, for the reason that the free edge, when the stitches are tied, is turned either upward or

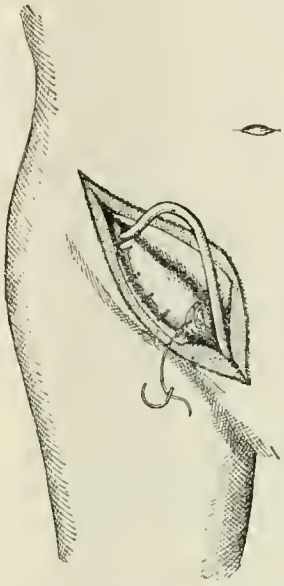

Fig. 4.

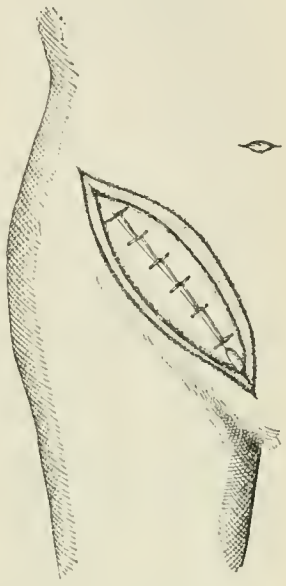

Fig. 5.

horizontally backward on the bone, for the force operating to open the canal is a vertical one and not, or only secondarily, a horizontal one as is persistently implied by Bassini, Marcey, and other authorities. The only horizontal or bursting force is that of the intestinal gases, which normally is just sufficient to balance the circulation in the cavity. On the contrary, the vertical force is powerful, acting from the diaphragm in its descent with the aid of gravity through the omentum and loaded intestines. This force may be compared to a wedge bounded by the muscles in front and on the sides, by the backbone to the brim of the pelvis behind, the diaphragm bounding the base and the edge resting on the pubis, its ligaments and connecting fasciæ. But at the moment of the slightest protrusion it becomes deflected in a horizontal direction, and it then proceeds through the canal as a vertical one. I consider Bassini's use of silk indefensible, as few at the present time will question that kangaroo tendon may be satisfactorily chromicized and reliably sterilized. In the healing process the silk stitches become encysted *in situ* without tension. With them in this position one might reason that should a sudden strain occur and tear the line of union the stitches would come into play and prevent total recurrence; but in answer to this one must remember that recurrences are gradual in their progress, and steady pressure would cause the sutures to cut their way through the least vitalized part of the tissues they included. Again an encysted foreign body is always a menace. Witness the many bullets that have lain quiescent since 1861, and at the present time have to be removed. That all perfectly sterilized silk is absorbed, and that all silk that is not absorbed even after years was not perfectly sterilized, appears to me to be an untenable position. Its use for ligating and tying off the omentum is far less defensible than for suturing; and yet when Professor De Garmo said, "Should I for any reason be compelled to give up kangaroo tendon I would go back to silk," he expressed their true relations at the present time. Dr. De Garmo's method of suturing the external oblique and the pillars of the ring by taking a wide stitch is, I think, a good one. The deeper layers have been reefed, leaving the external layer of the muscle just

that much slack; consequently when the pressure from the inside is directed against the wall, the deeper layer does not at once receive the support of the external layer. In regard to the sutures invented by me, the following are the directions for their insertion, also a new method using a Reverdin needle:

(1) Single-knot stitch (Fig. 8): The needle is passed through the divided tissues, and, without cutting the thread, a square knot is tied. For the second stitch the thread is held or thrown so that the needle will emerge in a loop, and, when it is drawn on through, a single knot will have been formed. The tension is now adjusted, and for the last stitch a square knot is tied. This may be modified by passing the thread around the needle or the needle around the thread. The tension of the stitches and between the stitches should be equal.

(2) The square-knot stitch: The same steps are taken as for the single knot, and when it is formed the needle is passed under the thread connecting the knots in the opposite direction from which the needle was inserted into the tissues.

(3) The friction-knot stitch: For the first stitch a square knot is tied, then the needle is passed as for a single-knot stitch, turning the thread twice around the needle instead of once. The last stitch is a square knot.

1st. With a Reverdin needle tie first as before for a single stitch, turn the thread around before inserting it; after it is inserted, thread the needle as is usually done, withdraw the needle, and the single knot will be tied. For a square knot put the needle under the thread between two knots, thread it, and withdraw.

2d. An assistant may form the knots while the surgeon passes the needle.

I wish especially to call attention to the fact that neither my single knot nor the double knot or friction knot suture is the buttonhole stitch commonly called Billroth's. Dr. Andrews, of Chicago, and Dr. Gerrier, of Paris, have both made this mistake. The reasons for their use I have somewhat elaborately set forth in the articles referred to, the chief of which is that they act at right angles to the line of approximation, and also

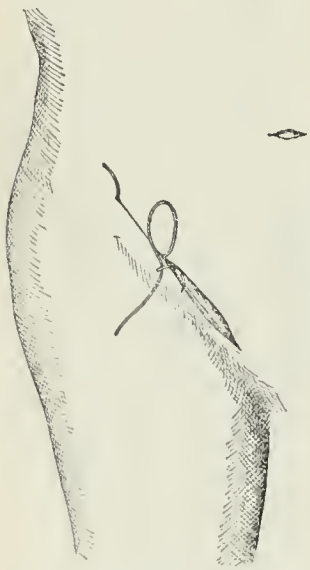

Fig. 6.—Third Step: De Garmo—showing the suturing of the skin with the subcuticular stitch.

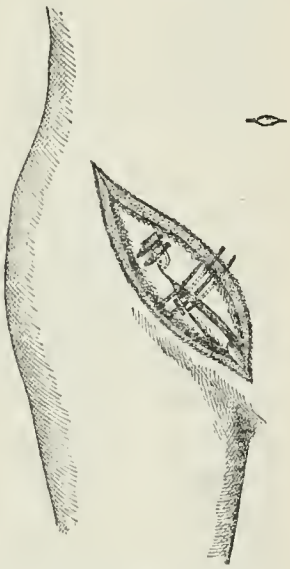

Fig. 7.—Lucas Championnière: Neck of sac turned under and held by two stitches; two U-stitches placed ready for tying.

longitudinally, comprising all the advantages of both the interrupted and the continuous stitches, and that they are much more quickly and more easily inserted, as one can sew with the single-knot stitch just about as fast as the needle can be passed; with a Reverdin needle where it can be used, with or without an assistant, the time is reduced so that it no longer figures in the operation. In doing the operation I follow the technique of Professor De Garmo in every detail, with this exception[1]: I use the square-knot stitch for the deepest layer, and I also now use the lap insertion. The blunt needle leaves the wound most satisfactorily dry, and especially when there is a tendency to bleed from sclerosis of the arteries. This needle is the only one that will take the first insertion of the deeper layer next to the bone and down to the shelving edge of Poupart's ligament, as the curve is just right. I do not know where the needles may be had, but no doubt a letter to Dr. De Garmo would obtain that information.

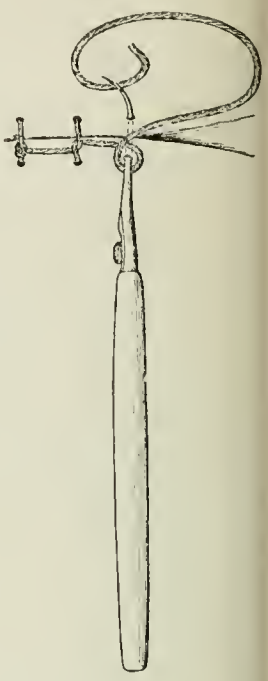

Fig. 8.

I have heretofore advocated a silk pelote or linen sponges for these and other operations, and still think it good practice. I have performed the operation five times since I returned from Europe, four on Italians, two of whom resumed heavy work in the Union Iron Works in five weeks, and are perfectly well at the present time. I see no reason for denying relief by operation to any person of any age from this distressing and dangerous condition. I have operated for hernia in a patient aged seventy-six, with perfect recovery in two weeks. In one case, with the assistance of Dr. McGill, I operated for a large scrotal hernia on a negro, with all the stigmata of age, gray hair, arterial sclerosis, pronounced arcus senilis, etc., who refused to consider himself confined to bed, and who actually went to work as chief cook on one of our large ocean liners at the end of one week, and who has suffered no return or inconvenience. Senility or age is a physical condition, not a question of years; consequently, an age limit is out of the question.

The operation for radical cure of hernia has the least mortality and the highest rate of perfect cures of any capital operation known to surgical science at the end of the century. It is a capital operation, and a long series of successful cases requires the most perfect technique known, the power to specify and to be exact.

Follicular and Periurethral Abscess in the Male.—Concerning this condition, W. F. Bernhart lays down the following rules: 1. Make sure of the diagnosis, for a follicular abscess may closely simulate a chancre or a gumma. 2. Try all the mechanical means available to produce an opening of the occluded duct or an absorption of the deposit. 3. Never await the breaking of a follicular abscess, as the destruction of the tissue is greater, or it may break both externally and internally, or it may rupture internally and point backward, thus favoring urinary infiltration. 4. Open through the urethra if possible.—*Memphis Medical Monthly*, April, 1901.

VARICELLA IN ADULTS.

By ALVAH H. DOTY, M.D.,
HEALTH OFFICER, PORT OF NEW YORK.

A WIDESPREAD belief exists that varicella, or chickenpox, does not affect adults, but is confined to infancy and childhood. That this is not true, and that chickenpox may occur after puberty, is fully understood by those who are familiar with these diseases. The teaching of the older text-books, which supported this erroneous idea, and which evidently did not represent a careful personal investigation on the part of the authors, is largely responsible for this belief. Unfortunately, but little effort has been made to bring this error to the attention of the medical profession. For this reason I desire to present for consideration some practical signs in the differential diagnosis of smallpox and chickenpox, which have a direct bearing on the matter referred to, and which if understood will enable physicians not only more readily to detect these diseases, but to appreciate that chickenpox occurs in a typical form in the adult. The signs which I refer to are as follows:

First. The character of the eruption.

Second. The manner in which the eruption appears.

Third. The distribution or location of the eruption.

The Character of the Eruption.—In studying the eruptions of smallpox and chickenpox it is essential that we should have a general idea of the tissue changes which take place in the skin, which are constant and give to each eruption its peculiar character.

In smallpox the eruption appears as circumscribed hyperæmic areas, the margins of which are very sharply defined, and which involves the true skin to a considerable depth and gives to the eruption in the early stages the sensation of shot placed just beneath the surface of the skin. Hence the term "shotty" which is so uniformly applied to the eruption of this disease. This tense and hard condition naturally disappears as the papular and vesicular stages are succeeded by the pustular, or when suppuration occurs. Inasmuch as the true skin is deeply involved the latter stage is followed by a permanent loss of tissue, the result of which is familiar to us all as the "pitting" of smallpox. The depth to which the true skin is involved is also responsible in a way for the hard and resisting vesicle, the top or surface of which can be removed only by considerable force, and for the comparatively slow manner in which the different stages of the eruption pass from one to the other.

The eruption in varicella is in marked contrast to the description just given. The vesicles are very superficial and only slightly involve the true skin. They contain either a transparent or pearly-hued fluid, and are soft and pliable and can easily be detached, and are short-lived. In appearance they resemble the small blisters that follow the application of some irritating substance to the skin. It is of great importance to fix in mind the superficial character and tenderness of the varicella vesicles. In order to illustrate this practically, it is only necessary to sweep quickly and firmly the edge of the finger-nail over the vesicle, in which instance the latter is easily torn apart. Sometimes a varicella vesicle may become irritated, or for some cause affect the deeper structure of the skin. This will account for an occasional scar which may follow the eruption of this disease.

The Manner in which the Eruption Appears.—In smallpox the eruption presents itself in one crop, *i.e.*, it passes through the different stages practically together as papules, vesicles, and pustules. In some parts of the body the formation of each stage or the transition from one stage to another may be a little more rapid than others; however, when this is finished the eruption is complete and secondary crops never appear. Too much importance cannot be given to this sign, as none other more closely approaches that of a pathognomonic character.

The manner in which the eruption of chickenpox appears is diametrically opposite to that of smallpox, inasmuch as it notoriously comes in successive crops. Alongside of vesicles which have dried down with the formation of a black or dark scab, we find small tender vesicles just appearing which are torn by a slight touch of the finger-nail. This is so strikingly apparent that it can hardly be overlooked even in a superficial examination. Moreover, the eruption of chickenpox appears abruptly as vesicles, and is not preceded by papules as in smallpox.

The Distribution or Location of the Eruption.—To bring this at once to its important practical application, I will state that in smallpox, even in mild cases, the hands and feet are to some extent almost always involved; whereas in chickenpox, even with a profuse eruption, the hands and feet are either unaffected or have but little eruption. The appearance of hard, tough, circumscribed, and distended papules or vesicles on the hands or feet, particularly on the palms and soles, is an exceedingly important diagnostic sign of smallpox. Even in mild cases we are quite sure to find a few along the fingers and toes and palms and soles. In varicella the hands and feet are often singularly free from the eruption even when it is profuse on other parts of the body. In other cases a small number of spots may be found about the hands and feet, but they are few in comparison with the eruption in other parts of the body; besides, they do not often appear on the palms of the hands and soles of the feet. However, when this occurs, their nature will as a rule be made clear if they are considered in connection with the eruption on other parts of the body.

I may add that the back presents the best surface to study the eruption of varicella.

In regard to umbilication, which in the older text-books is spoken of as the pathognomonic sign of smallpox, I would say that it is a well-marked, constant, and valuable diagnostic sign of smallpox, but what will pass for and is regarded as umbilication is frequently found in chickenpox and some forms of syphilitic eruptions. This must be kept in mind.

I do not intend to present a treatise on smallpox and chickenpox, but desire to direct attention to only three signs, which I believe to be of great practical value in the diagnosis of these diseases. When these are fully understood, then signs and symptoms of less importance may be considered. Under all circumstances it should be borne in mind that the diagnosis of smallpox and chickenpox is made from the appearance of the eruption. I have made no reference to the constitutional symptoms; that these are important as corroborative evidence is true, but I believe they should be considered after the eruption has been studied. The more proficient one becomes in the diagnosis of smallpox or chickenpox the less he relies on constitutional symptoms.

Some time ago a vessel arrived at this port having on board a typical case of smallpox. Although the ship's surgeon had isolated the case, he reported that he did not believe that the patient was suffering from smallpox, as he had practically no fever and other constitutional symptoms were not present. I cite this instance simply to illustrate the error of giving constitutional symptoms undue consideration.

Within the past ten days two typical cases of chickenpox in adults have arrived at this station from foreign ports: one, a member of a ship's crew; the other, a second-cabin passenger. Cases of this character not uncommonly present themselves, and they will as a rule

be detected if the signs which I have referred to are carefully studied. I have made no reference to obscure or irregular cases of smallpox or chickenpox which from time to time present themselves. It will be of interest to note that these diminish in number as a physician becomes more practically familiar with these diseases.

Although it may not be pertinent to the subject of this article, I wish to say that I cannot too strongly condemn the use of the term "varioloid" which is variously accepted as indicating a mild, less dangerous, or distinct type of smallpox. The use of this term unquestionably tends to carelessness, as in these cases there is commonly a relaxation in the usual precautions taken to prevent the extension of smallpox. Therefore cases of "varioloid" are apt to be of special danger to the public health. Although "varioloid" represents a mild attack of smallpox, it is capable of producing in others the most malignant form of this disease.

Quarantine, April 18, 1901.

A PLEA FOR THE CONSERVATION OF BREAST MILK IN WHOLE OR IN PART.[1]

By THOMAS S. SOUTHWORTH, M.D.,

NEW YORK,

ATTENDING PHYSICIAN, NURSERY AND CHILD'S AND RANDALL'S ISLAND HOSPITALS; PHYSICIAN, OUT-PATIENT DEPARTMENT, BABIES' HOSPITAL.

There are probably very few practitioners to-day who do not acknowledge an ample supply of normal breast milk to be the best and safest nourishment for an infant. The great majority of the medical profession undoubtedly are aware of the difficulties and dangers which attend bottle-feeding, so that it is almost superfluous to recall the fact that ninety-seven per cent. of the infant mortality from gastro-intestinal diseases occurs in those who are nourished otherwise than exclusively from the breast.[2] Were statistics also available, based upon these two forms of feeding, so that we could compute with these deaths from gastro-intestinal diseases the deaths occurring among the bottle-fed from those conditions variously classed as athrepsia, marasmus, and malnutrition, and equally important those from broncho-pneumonia, the infectious diseases, and a host of other troubles to which the poorly nourished are more liable, and to which they more readily succumb, we should without doubt find both the morbidity and the mortality of the bottle-fed to be startlingly in excess of that of nursing infants. The official statistics of the German government show that of artificially fed infants fifty-one per cent. die during the first year, while only eight per cent. of those exclusively nursed perish during the same period.[3] We cannot then but feel that the larger part of the disease and death among young children results both directly and indirectly from the state of their nutrition, and that a very considerable part of both would have been avoided could the children have been intelligently nursed.

Yet the fact that artificial feeding is on the increase to the exclusion of maternal nursing will scarcely be denied by observant physicians, whatever the class of patients among whom they practise. Numerous factors enter into the etiology of this situation. To the fashionable mother whose child suffers, because, although abundantly able, she is selfishly unwilling to fulfil her maternal duty to her offspring, we can give neither sympathy nor consideration. The unhygienic influences of much of our boasted civilization, together with the mental pressure of our modern educational system upon the growing girl, and the consequent stimulation of the nervous system at the expense of the body at a critical period of her development, as well as the physical pressure of outgrown and tight corset waists and ill-fitting corsets, are everywhere producing a host of undeveloped and malformed women who will swell the number of incompetent mothers in the next generation. The incursion of women into the fields of labor formerly occupied exclusively by men, and their subsequent unwillingness or inability to relinquish these duties after marriage, are responsible for still other instances; while the subtle encouragement given by the multiplication of asylums, homes, and day nurseries, to the practical abandonment of the child, while the mother seeks employment, still further swells the number of the bottle-fed.

Excluding all cases in which it is impossible for the mother to suckle her infant, there still remains an even greater number of instances in which the infants are prematurely deprived of their natural food on account of the absolute ignorance of the mothers as to the simplest principles of nursing and of the means of conserving a normal mammary secretion. The blame for this does not attach to the mothers. The ultimate responsibility for this condition of affairs lies with the medical profession. It is definite and cannot be evaded. It falls upon the family physician, who has ample opportunity to advise concerning the education and dress of the growing girl, and upon the examining physicians and members of the medical boards of maternity hospitals and institutions for children. But the chief, because the most direct, responsibility attaches to the obstetrician and the general practitioner who attend confinements and care for the mother and child during the first days or weeks of infancy, for it is during this period that the subsequent nourishment of the child is usually determined. Here, then, is the opportunity to acquaint the mother with the dangers which the child will run if deprived of the breast without adequate cause. Here is the golden and fleeting opportunity to start the child rightly and safely upon such form of nourishment as can be made available, and to instruct the mother as to her diet and personal health if she is to nurse her infant. Yet at this all-important time there are the greatest indifference and neglect. This, perhaps, is hardly to be wondered at, when one considers that as late as a decade ago students were graduated by thousands from the medical schools of the country with scarcely a word upon the feeding of the young infant. As these men now form the majority of the practitioners, it is little to be wondered at that the obstetric aspect of a birth engages their attention to the exclusion of all else, and that, when the cord is tied and the child has shown reasonable evidence of vitality, it is turned over to the tender mercies of some nurse or relative, and thenceforth passes practically, if not absolutely, out of consideration unless some matter out of the ordinary arises.

Let us pause a moment to ask this question: How many of those who hear or read this paper are in the habit of carefully regulating the nursing of the infant, or of definitely outlining the artificial feeding of the infant for the succeeding weeks before they make their last visit in an ordinary confinement case? Even if this question could be answered in the affirmative by the majority, which is, it seems, extremely doubtful, how many of these are in the habit of specifically indicating the proper diet of the nursing mother in order that she may nurse her infant to the best advantage and maintain the supply of proper quality for a reasonable period? That minute directions of this nature should be necessary seems strange when we think that all other mammals suckle their young successfully under the infallible guide of instinct. This was

[1] Read at the meeting of the Medical Society of the County of New York, April 22, 1901.

[2] Holt: Keating's "Cyclopædia of Diseases of Children," vol. iii., p. 64.

[3] Winter: "The Feeding of Infants," p. 2.

doubtless the case also in the earlier days of the human race, before development in higher directions had obscured those intuitive leadings which are the possession of all animal life in its native state. Be that as it may, however, the maternal instinct to-day seems to teach only that the child is hungry when it cries, and that it may be quieted by engaging its attention with the breast, and beyond that absolutely nothing. The invariable answer of the young and ignorant primipara, when asked how often she nurses the child, is, "As often as it cries," or "Whenever it looks for it!" Under aboriginal conditions, with strong children and abundant milk, this may be sufficient when satiety would be followed by a considerable period of placid contentment, broken only by renewal of hunger when normal digestion was at an end. But the moment the health of the child or the quantity and quality of the maternal breast milk fall below the normal, what should be a protective or conservative instinct begins to lead directly into error, for it is not a too positive statement when it is affirmed that, despite the accumulated experience of centuries, not a ray of intuitive knowledge of how to nurse under abnormal conditions, or how to conduct artificial feeding, is as yet discoverable in the human race. What wonder, then, that, if the physician does not step in, the feeding of the child will be based upon hearsay, or ignorant custom, or tradition, and will be influenced by considerations of convenience or cheapness?

A service of nine years in dispensaries for the children of the outdoor poor, in the conduct of which it has been his aim to investigate the histories and to devote time and attention to each patient as carefully as would be the case in private practice, must be the author's ground and excuse for these dogmatic assertions. While acknowledging that a considerable portion of the profession have grasped and are daily testing and expanding the recently expounded principles of infant feeding, and that many others are endeavoring to do so, as attested by the interest displayed when this matter is the subject of discussion in our societies, it becomes patent from the evidence of the mothers who present their children for treatment at the clinics that, in the new enthusiasm over methods of artificial feeding, the importance to the child of the maternal nourishment may be quite overlooked and forgotten.

It is high time that the profession should give deep and thoughtful consideration to this problem. The medical press contains frequent articles upon artificial feeding, which refer, it is true, to the dangers of bottle-feeding, but accept the abandonment of the breast as an inevitable evil without any effort to strike at its root by offering practicable suggestions which may render such abandonment unnecessary. However perfect may be our measures for artificial feeding, we still find that in the aggregate these children do not thrive so well as the breast-fed child. Modifications of cow's milk are vastly superior to infant foods. They approximate more nearly to the natural nourishment of the infant. But the composition of cow's milk and human milk is not the same, and no amount of modification will make them exactly the same. We do know that the various proteids in the two differ in their relative proportions; but we can as yet only vaguely surmise the influence upon the infant of the immunizing and protective principles or the aids to digestion and normal growth furnished and adapted to the young of its own species by the secretion of the human breast. Let no one mistake our position for an attack upon modifications of cow's milk and the recognized value of percentage feeding when maternal breast milk is not available. But rather let it be clearly understood as a protest against any subtle tendency to the belief that, as a profession, we are yet fully warranted in substituting the bottle for the breast for young infants unless we have conscientiously exhausted every known means of maintaining the maternal milk.

The clientèle of an infants' clinic is naturally composed of the sick and not of the well. It is there, therefore, that we see, not the brilliant successes in artificial feeding, for the well-nourished infant not only does not need the physician, but by very reason of his good condition has at least a fifty per cent. better chance of escaping major and minor ailments, but rather the dismal failures in nutrition which flock to our doors. Therefore we believe it to be the function of such a clinic not only to treat the patients, but to discover the causes of illness and, if possible, to make known the remedies. In taking the histories of the puny infants who are brought to us as a last resort, after their parents' uniformly unsuccessful attempts to nourish them upon a variety of infant foods, the questions are usually asked: "Was the child nursed?" "If so, how long, and for what reason was nursing abandoned?" "If never nursed, why not?" From these questions it has developed that, while a certain proportion have never been nursed for what were accepted as good and sufficient reasons, such as no milk, depressed nipples, or serious illness of the mothers, the majority of these children have been nursed for periods varying from a few days to two or three months, and then a sudden change has been made to artificial feeding.

The reasons for this change are usually that the child did not thrive or that the milk did not agree, and that by the advice of friends, and too often also on the recommendation of a physician, artificial feeding was at once substituted. In a lesser number of instances it is stated that there was thought not to be enough milk in the breasts, and that on similar advice nursing was promptly abandoned. Again, in perhaps the smallest number of cases we are simply told that the milk gave out and that the lack was supplied by some substitute. But in only the rarest instances could it be learned that any systematic attempt had been made, even when under the care of a physician, to maintain or improve the supply of breast milk other than by the use of malt beverages, or occasionally of malt extracts. Furthermore, and perhaps still more surprising, no value had seemed to be placed in these early cases upon such breast milk as might still have been available after artificial feeding had been begun, except, perhaps, as a means of stilling the cry of the child at night, and thus incidentally of encouraging the disastrous habit of frequent night nursings. In short, there seems to be a widespread ignorance or disregard of the fact that the secretion of the human breast is as readily influenced by diet and hygiene as that of the udder of the dairy cow; also that close confinement all day in a stuffy apartment, and a diet which consists largely of strong tea, are not conducive to a secretion of suitable quantities of fat, milk sugar, and proteids in the breast milk. From the almost total lack of consideration of the subject one would be led to think that breast milk were a sort of manna sent each day from heaven, and having no bearing or dependence upon the diet and nutrition of the mother.

The adult of average weight throws off from the body in twenty-four hours sixty-nine to eighty-nine ounces of water, divided as follows:

Lungs	9 oz.	to	9 oz.
Skin	20 oz.	"	30 oz.
Urine	40 oz.	"	50 oz.
	69 oz.	to	89 oz.

To this must be added during lactation twenty to forty ounces secreted by the breasts, which, added to the above figures, gives a total of eighty-nine to one hundred and twenty-nine ounces, or, if an average is struck between these extremes, let us say one hundred and

nine ounces, or more than the equivalent of three quarts of fluid. Confronted with these figures, one realizes at a glance that the fluid, even including that contained in the solid food, taken by the average woman at each of the three daily meals would rarely reach one quart per meal, and that if three quarts and more are to be ingested during the twenty-four hours, it must be drunk freely between meals. Yet many women of the lower and middle classes seldom take of their own accord any fluids except tea, coffee, and beer. If from these beverages they are to supply the water necessary for normal excretion and secretion, it is apparent that the amounts ingested would carry with them quantities of stimulating principles which cannot but be hurtful, while the food values, except perhaps in the case of beer, and the fat-, sugar-, and proteid-making values are practically nil. From the very evident absurdity of the foregoing proposition, when worked out to a conclusion, the necessity becomes apparent of drinking water freely during lactation, or, much better, milk, thin gruels, and cocoa, which have definite food- and milk-making possibilities.

It is not among the lower classes alone that this tendency to take too little fluid prevails. If insufficient quantities of fluid are taken by any individual, the health is liable to suffer through constipation, due to dryness of the fecal masses, and more or less poisoning by effete matters, which should be thrown off by free and normal diaphoresis and diuresis. These conditions exist *par excellence* in tea-drinkers, and it is probable that as tea and allied beverages assuage thirst more quickly than plain water, less is consumed in a day. If now during lactation, in which there is, as has been seen, an additional demand for twenty to forty more ounces, the supply of fluid is not increased proportionately, there will be either a falling-off in the amount of milk secreted, or a still further reduction in excretion, or, in all probability, a lessening in the amount of both. Furthermore, it is seriously to be suspected that, when the emunctories of the mother are not acting properly, the secretion of the breasts contains effete and injurious matters.

What, then, are the measures which, when adopted immediately after parturition, favor the establishment and continuance of a breast milk sufficient for all needs of the infant? In these days of aseptic and afebrile midwifery there is no reason in keeping the healthy parturient for days on a low diet. During labor but little fluid is taken, while perspiration and hemorrhage directly reduce the fluids of the body. As soon as the mother is rested after parturition, or has recovered from the effects of the anæsthetic, she should be given bouillon, milk, or gruel in increasing quantities at the usual intervals of fluid diet (every two or three hours), and these should be continued for twenty-four hours. Then on the second day, while a liberal fluid diet is continued, there may be added easily digested semi-solid food, dropped or lightly boiled eggs, custard, rice, farina, etc. On and after the third day meat is allowed, with as liberal a diet of plain digestible food as seems suited to the individual; water, milk, gruels, and cocoa being insisted upon both with and between the more important meals. At this time it should be made clear to both mother and nurse that this additional fluid food is not a temporary measure, but must be continued throughout lactation in the interest of the infant. Abundant experience has shown that yellow cornmeal gruel is much more effective than any other gruel, and should be insisted on specifically. Thoroughly cooked and made, either with or without milk, as a thin gruel and salted, it is quite palatable, and should be drunk by the bowl—not by the cupful. Tea should be prohibited, and cocoa, made by long boiling of the "cracked cocoa" bean, substituted. It is a better stimulant and milk-maker than the so-called cocoa powders, which are practically chocolates, and does not disturb the digestion. The mother should be apprised of the great importance of adhering strictly to regular hours and intervals of nursing, and a schedule of nursing hours written out, covering the first three months. The second day after childbirth the bowels should be moved by a laxative, of which, from the standpoint of the mammary secretion, castor oil in full dose (℥ i.) stands preeminent. Mild salines may be chosen if indicated, but in general salines should be avoided in nursing women, as the watery stools decrease the mammary secretion. Constipation should never be neglected during lactation, but should be overcome in the interests of both mother and child; for this purpose cascara is especially suitable. Should the milk come into the breasts scantily, or threaten to disappear, the stimulating effects of breast massage should not be forgotten, and efforts should be made to hasten the mother's recovery by allowing her to sit up in bed as soon as possible, and to be out of bed at the earliest day compatible with proper uterine involution. Cheerful encouragement of the mother, when any anxiety concerning the child is developing, often turns the scale favorably, and fresh air and outdoor exercise also play their part. Anæmia, which would excite remark and receive treatment under any other circumstances, is often, nay, usually, disregarded after childbirth. Iron should be given early if indicated, and continued till the hæmoglobin approaches the normal.

The cases which are later presented to us for advice and treatment because the breast milk is thought to be at fault may be divided into two general classes:

Class I. Children who appear from a comparison of their present weight and age to be gaining satisfactorily, but who are said to suffer from vomiting, colic, crying, or disturbed stools. The primary test in cases of this class should be: Is the child really still gaining steadily in weight? This may be determined by weighing the infant without clothing in a suitable scale,[1] and again weighing it after the lapse of two or three days. If the appearance of the child be presumptive evidence of good nutrition, and especially if this be proven by successive weighings, the prognosis of the other ills is almost uniformly favorable. The diet of the mother is always investigated and corrected, but frequent and irregular nursing, "whenever the child cries" or "seems to want it," proves to be the most common cause of disturbances of this class, and most of the cases are set right chiefly by a simple regulation of the nursings to proper and exact intervals and a reduction of their number during the hours from 10 P.M. to 6 A.M. Colic, crying, and disturbed stools, the symptoms of indigestion from over-feeding with milk of varying composition, owing to variation in the nursing intervals, are thus remedied and avoided. Disappointment is often evinced by the mothers, at first, when they find that no medicine is ordered for the babies, but a little patient explanation will make them willing to follow the recommendations, and since the resulting improvement can be ascribed only to their own diet and the regulation of the nursings, the lesson to be taught is thus more definitely impressed. Spitting up, which results from a greedy ingestion from the breast of a larger quantity of milk than the stomach will accommodate when peristalsis begins, may be entirely disregarded if the child be shown by the scales to be gaining regularly in weight. Spitting up from excess of fat in the milk may be overcome by

[1] Since scales, combining both the platform and the scoop, and weighing accurately from half an ounce to two hundred and forty-four pounds, can now be obtained at a cost of $3 or less, they are within the reach of parents of even moderate means, and of every physician for office use.

changes in the mother's diet and the withdrawal of alcoholic and malt beverages. Still other cases yield readily to small quantities (ʒ ii.) of lime-water given some minutes before nursing.

Class II. Children who do not appear to have thriven on the breast, as attested by their small weight as compared with their present age and their size at birth, *i.e.*, whether small, average, or large.[1] In addition to the small weight there may be added colic, crying, short periods of sleep, and disturbed stools. This is probably the class in which the milk is so often declared to be useless, which leads most frequently to abrupt weaning and the substitution of some artificial food or mixture. Although doubtless such a change is often followed by brilliant results, it must be held responsible for a definite amount of the infant mortality from the early or late accidents attendant upon artificial feeding. It also furnishes us with a considerable proportion of our malnutrites. When such a case is presented, the child is undressed and its exact weight down to half ounces is at once taken and recorded. Spring and dial scales, which register only one-quarter or one-eighth of a pound, are notoriously unreliable and worse than useless for this purpose when small differences must be taken into account. This accurate weighing of the child is of prime importance, for by comparison with subsequent weighings made every second day one can alone determine the immediate results and decide upon the continuation or change of the remedial measures. The breasts of the mother are then inspected, and, with such aid as can be gained from questioning concerning the mother's own impressions and sensations and what can be learned of the behavior of the child at the breast, an attempt is made to form some sort of opinion as to the amount of secretion. This, of course, may prove to be deceptive. In hospital wards and private practice weighing both before and after a succession of nursings gives definite information on this score.

If the condition of the child is fair, and not absolutely threatening, the first and only indications at this time are to regulate strictly the frequency of the nursings and to correct the mother's diet, adding the fluid forms of nourishment above mentioned, with a view of regulating the infant's digestion and increasing and improving the milk supply. The child is subsequently weighed at intervals of two days, and the results are noted and compared. In a few days we may usually be able to judge pretty accurately of the present and prospective success of these methods. In the majority of cases our experience is that the child shows an immediate gain in weight, or else holds its own at first with a stationary weight, which is followed after a few more days, during which the breast milk is improved, by a gain which is continuous, and the progress of the child is thenceforth uneventful.

If, however, upon close observation there is a continuous loss or a persistent stationary weight, showing that the breast milk cannot be increased to supply all the needs of the child, the indications are for the beginning of supplementary feedings, and by no means for abrupt weaning, as long as the breasts contain any milk worth mentioning. In like manner, if at the first visit the condition of the child is such as to render definite nutriment imperative, or there is good ground for the belief that the breast milk cannot be built up sufficiently to supply all the needs of the child, no effort should be spared to stimulate rationally the secretion of milk, but some supplementary feedings are given tentatively at once. If the matter be urgent, the bottle is given, alternating with the breast, every two hours. If less urgent, two bottles are preferably given, one in the morning and one in the afternoon, in the place of nursings. Two such bottles are often enough to turn the scale and inaugurate a gain in weight. It should never be forgotten that a weak modification of milk digested and absorbed will produce this desired result, when a modification a little too strong would produce indigestion and utterly defeat the purpose. If two bottles prove insufficient to secure a gain, others may be added with caution more or less rapidly; but breast-feeding should, if possible, be maintained as often as every alternate feeding, for with this frequency the secretion is less liable to suffer. Moreover, there is good ground for believing, as breast milk is more readily and more completely digested than cow's milk, that bulk for bulk it furnishes a larger proportion of material for growth, while the alternation of bottle and breast allows of at least a four hours' interval between any two bottles. The proteids of the cow's milk thus have ample time to be digested, and there is less danger of the digestion being overtaxed than there would be if more of the proteids of cow's milk entered the stomach before the preceding bottle-feeding was entirely disposed of. It is doubtless partly for this reason, then, that, when an all-breast milk diet cannot be furnished, the infants who are nourished upon part bottle and part breast progress, as a rule, more steadily and uneventfully than do those who receive the bottle alone. Furthermore, by thus maintaining the secretion of the maternal breast, one is in an infinitely better position in the event of digestive disturbances or intercurrent disease, especially during the hot season, for it is then possible to fall back temporarily upon the easily digested breast milk alone. In some cases the increasing amount of breast milk under proper diet and hygiene allows later of dropping some or all of the supplementary feedings.

The importance of conserving the maternal milk in connection with such artificial feedings as will eke it out has received but little recognition. Some of the laity, and even occasional practitioners, are still found who believe and maintain that it is unwise or dangerous to give the child the two kinds of milk together. Several years ago, at the Infants' Hospital on Randall's Island, before the efforts of the medical staff for the establishment of an adequate milk laboratory had been crowned with success through the private generosity of Mr. Nathan Straus, the mortality of the bottle-fed infants under one year was very high, but that of foster-children, nursed by the wet-nurses in addition to their own children, was also most discouraging. Through the efforts of the author and his associates, the system of alternating nursing at the breast, with more or less supplementary bottle feedings, has been brought into general use with most satisfactory results, as attested by the condition and growth of these infants, which far excels that of the exclusively bottle-fed; for, contrary to the old belief, few women in institutions can furnish breast milk enough for the proper nourishment of two infants, and it is the foster-child that almost invariably suffers. This system of part breast and part bottle is apparently the only solution of the problem of mortality in foundling hospitals, as the recent statistics from Randall's Island amply demonstrate.

In almost all institutions, however, which provide for nursing women and young infants, there is the utmost disregard of the diet and hygiene of the women who are there to produce breast milk. Strong tea is served at nearly every meal and liberally drunk by the women. Milk to drink is often theoretically supposed to reach them, but it is left to a woman's own preferences whether she takes it or not. Pale, anæmic, and poorly fed, she sits all day listlessly about the ward,

[1] Birth weights as reported by mothers are almost invariably unreliable. They are usually mere guesses by the physician, nurse, or friends.

or is assigned to some more active duty in-doors. Methods the equivalent of these applied to cows would soon ruin the dairyman, yet these women are paid or receive benefits in return for the milk which they can furnish. Why, then, should they not be under closer supervision, and be supplied only with such nutritious and wholesome food as will enable them to give good milk and the largest possible quantity?

During the house service of Dr. J. C. Roper at the Nursery and Child's Hospital (January 1 to May 1, 1900), the nursing mothers and wet-nurses were stringently required to walk or be in the open air for one to two hours daily, while their diet was enlarged and supervised on the lines mentioned above, with the result of improving the supply of breast milk both in quantity and quality. This enabled them to supply breast milk to a larger number of orphan children than would otherwise have been possible. The women thus cared for during the winter and spring months were the only ones who successfully nursed their children through the summer. No further demonstration was necessary, to those who watched this experiment, of the feasibility of favorably influencing the secretions of the breast by these measures.

Since this paper was begun, the author has been pleased to find that Dr. Koplik, in his paper read before the American Pædiatric Association in June 1899,[1] advocated the utilization of part breast feeding when possible. It seems as if this must have been the conclusion reached by every one who has struggled thoughtfully and conscientiously with the problems of infant nutrition, yet it has scarcely found a place in the literature of the subject. On all sides the impression is found that as soon as a child digests several feedings daily from the bottle it is a matter of little consequence how soon the weaning is completed. The nearer the end of a normal child's first year approaches the more truth there is in this position. But if it be in the first few months or half year, I do not hesitate to assert that such early weaning to the bottle is fraught with very serious dangers to the child. The career of the infant whose food is in part at least breast milk is much more likely to be uneventful. The direct and indirect dangers of digestive disturbance and varying grades of malnutrition in those who receive the bottle alone can scarcely be set forward too strongly. Let no one count it a light matter, then, to advise the early withdrawal of the breast, for in so doing, in no small proportion of cases, the child's life hangs in the balance. What matters it that the mishaps may be postponed weeks or months? But, because they are postponed, the fatal outcome of the gastro-enteritis or broncho-pneumonia, or infectious disease, or rachitic convulsion is none the less due to the malnutrition of bottle-feeding.

Cataract Formation after Lightning Stroke.—J. Preindlsberger has observed this event three times as a sequel to lightning stroke. One case was that of a man aged twenty-four years, who was thrown from his chair and rendered unconscious for ten minutes by the bolt. Difficulty with vision began a month or two later and progressed until even the power of finger counting was lost. The other two patients were brothers who were struck simultaneously and remained unconscious for some time. Shortly after the accident the vision was rosy, but improved again, only to be almost entirely lost in the course of time. In all three patients other causes for the formation could be excluded, and operation was followed by fair functional results.—*Wiener klinische Wochenschrift*, March 28, 1901.

ON BANDAGES FOR NEPHROPTOSIS.*

By GEORGE M. EDEBOHLS, A.M., M.D.,
NEW YORK.

As early as 1841, in his epoch-making memoir on the subject of movable kidney, Rayer[25] advocated the wearing of an abdominal bandage for the relief of the condition. Oppolzer,[23] fifteen years later, followed with a—for that time large—statistical contribution, in which he condemns the bandage as useless. Of the earlier writers, the majority advocate some form of artificial support. Later, after operative fixation of the kidney was proposed and performed by Hahn, in 1881, and as nephropexy gradually became established as a legitimate and successful operation, the advocates of the bandage treatment became relatively fewer and fewer.

Simple bandages, consisting of either a supporter or belt enveloping and sustaining either the whole or a part of the abdomen, were recommended by Herzka,[13] Zuelzer,[32] Douglas,[4] Miller,[19] Willmore,[31] Bevill,[3] and by Rose,[26] the latter advocating support by strips of adhesive plaster, more especially in cases of gastroptosis, although his device answers equally well in cases of movable kidney. These simple supports are rational in that they act by supporting the entire contents of the abdomen, in this way sustaining and more or less immobilizing the movable kidney or kidneys. They are most satisfactory in cases of movable kidney or kidneys associated with general enteroptosis. When movable kidney exists and produces symptoms in the absence of general enteroptosis, supporting bandages of any kind, including the low-reaching corset, will prove unsatisfactory.

Bandages, trusses, and belts, with special kidney pads, have been devised in great number. Ellinger[10] and Lindner[16] have described such special apparatus. Smith,[29] Niehans,[22] and Suckling[30] use a truss with a kidney pad; Stewart[27] uses a belt and pad. A supporting bandage with an air pad over the kidney was first recommended by Newman,[21] and subsequently by Le Cuziat[14] and Stifler,[28] while Lockhead[17] recommends a belt and rest.

Before discussing the various appliances with a kidney-pad feature, it may be of interest to summarize briefly the various other methods of treatment, exclusive of nephropexy, advanced for the cure of movable kidney. Of these measures, the only one that deserves serious consideration is general massage, either alone or combined with the rest cure. Massage of the kidney itself, as will be shown farther on, is injurious, and therefore to be avoided. Bachmaier,[2] Fellner,[11] and Eccles,[8] among others, have written on this subject. Other measures proposed possess interest simply as therapeutic vagaries. Such are the proposition of Newhall[20] to cure by electricity, applied by placing one pole over the kidney and the other in the vagina; of Abrams,[1] who believes he caused adhesions of the kidney by applying over it collodium cum cantharide; and of Raichline,[24] who succeeded in one case with hypodermic injections of renal extract or renine. Le Gendre[15] advocates diet and strychnine to reduce meteorism, while Gurzburg, per contra, as quoted by Fischer,[12] administers a yeast ferment, with the object of producing meteorism, and thus sustaining the prolapsed kidney.

I shall now endeavor to show why all appliances devised to maintain a movable kidney in place by direct pressure upon the displaced organ exerted by means of a special kidney pad are not only illusory but really harmful.

In the first place, it is difficult, nay, impossible, for any one who has had even a moderate experience in

* Read before the Medical Society of the County of New York, April 22, 1901.

the examination of patients for movable kidney to understand how any pad can be contrived from the pressure of which a freely movable kidney will not escape. With the patient in the upright position, it is practically impossible to maintain a movable kidney securely in place for any length of time by the pressure of one hand applied ever so intelligently. The well-rounded, smooth organ, embedded in fat, escapes most provokingly in the direction of least resistance. How much more elusive, then, must it prove to any mechanical contrivance! With the patient standing, it requires two hands, one pressing from in front and the other from behind, with the fingers meeting below the lower pole of the kidney, or a similar grasp between the thumb and fingers of one hand, to sustain a movable kidney in place. No form of kidney truss has, to my knowledge, yet been presented with two pads—one pressing deeply into the hypochondrium and the other into the lumbar region, and no patient could be found capable of enduring the pressure necessary to sustain a movable kidney above two such pads and to prevent it from gliding down between them.

In the next place, such pressure, even if it could be endured by the patient, or a lesser degree of pressure, even if it could be applied to the kidney, must, according to the researches of Menge,[5] prove positively harmful. Menge found that even the pressure exercised upon the kidney in performing diagnostic palpation is not a matter of indifference. He examined the urine before and after palpation of the organ in twenty cases of movable right kidney and in one case of mobility of both kidneys. In six cases only were the urinary findings the same before and after palpation. In fifteen cases in which the urine was found normal just before palpation, it always contained albumin and a little blood after palpation. Albumin was always found in greater quantities than could be accounted for by the amount of blood present in the urine. He states, indeed, that we may have a pure albuminuria without blood corpuscles. He concludes that the albuminuria and its degree depend, probably, upon: 1. The vigor and duration of the kidney palpation. 2. The nutritive condition of the patient. 3. The tension or tonicity of the abdominal walls. 4. The degree of nephroptosis. 5. Indefinite conditions which we may group as "sensitiveness of the palpated organ." As a result of his investigations, he warns against massage of the kidney and against bandages with special kidney pelotes or pads.

The above observations seem to sustain the wisdom of Nature in placing the kidneys in the well-protected location they normally occupy. They may also help to explain some clinical observations of the writer in connection with his work in operative fixation of movable kidneys. In two hundred and forty-one nephropexies performed upon one hundred and seventy-six patients I encountered no less than nineteen kidneys affected with chronic interstitial nephritis and two with acute nephritis. In the fourteen patients affected with chronic nephritis the disease was confined to the right kidney in six, to the left kidney in three, in five it was bilateral. In other words, it was unilateral in nine, bilateral in five only, a fact pregnant with meaning and hope to sufferers from chronic nephritis. These findings seem to indicate that Bright's disease is proportionately more common in patients with movable kidneys than in individuals with kidneys in place. Is this because of circulatory disturbances connected with the displacement, or is it because a movable kidney is more exposed to various traumatisms than one well up beneath the ribs, or are both causes active in producing the result?

In connection with these eighteen nephropexies performed upon patients with chronic nephritis, the interesting observation was made that a cure of the nephritis followed operative fixation of the kidney in a large proportion of cases. Albumin and casts disappeared permanently from the urine. My earlier observations in this direction were published two years ago under the heading: "Chronic Nephritis Affecting a Movable Kidney as an Indication for Nephropexy."[6] Growing experience has added confirmation to the deductions drawn in this paper, and I am now prepared to go a step farther and propose surgical intervention for the purpose of attempting a cure of chronic nephritis, whether the affected kidney be movable or in place. The surgical intervention, as in my practice heretofore, is to take the form of a nephropexy with denudation of the kidney cortex when the kidney is movable. When the inflamed kidney is not movable, and operative fixation of the organ is, therefore, not indicated, I shall content myself with entirely denuding the kidney of its capsule proper, and thus affording free opportunity for the formation of new vascular connections, on a large scale, between the blood-vessels of the kidney and those of its fatty capsule. The relief to the kidney circulation by the establishment of an abundant collateral circulation, which, I believe, has been the chief factor in the production of the favorable results I have thus far obtained in the cure of Bright's disease affecting a movable kidney, will thus be applied to all chronically inflamed kidneys, whether movable or not. The rationale of the procedure will resemble, though with a distinct difference, that which applies to the modern surgical treatment of ascites due to cirrhosis of the liver. The writer is at present engaged in collecting from his operative clinical experience the evidence bearing upon this subject, with a view to its presentation in print in a fuller and more formal manner.

A third reason why a special kidney pad should never be applied is based upon the relations of movable right kidney and chronic appendicitis, to which the writer[7, 8, 9] has repeatedly drawn attention. It is my firm conviction, based upon painstaking clinical observation, that more or less congestion or inflammation of the vermiform appendix is present in nearly all cases of movable right kidney producing symptoms, and these cases are the only ones that call for treatment.

This conviction has been but strengthened by enlarging experience. Thus, in the last seventy-four patients upon whom I have performed nephropexy—unilateral in thirty-three, bilateral in forty-one—since June, 1898, chronic appendicitis was found and the appendix was removed, by inversion or excision, in no less than fifty-four. Of these fifty-four diseased appendices, eight were removed prior and one subsequently to the date of nephropexy; while in forty-five cases the appendicitis was operated upon simultaneously with the performance of right nephropexy through one and the same lumbar incision. Every special kidney pad, by virtue of its pressure above the region of the appendix, must interfere more or less with the return circulation of that organ, and must on that account prove injurious and dangerous.

Summary: Bandages for movable kidney may be divided into two general classes:

1. Simple bandages, and apparatus embodying the feature of a special kidney pad.

2. Simple bandages act by supporting the entire contents of the abdomen, sustaining and more or less immobilizing the movable kidney or kidneys on top of the intestinal mass.

3. All the relief to be gotten from bandages in cases of movable kidney, is obtainable from one of two devices, either from an elastic bandage, encircling and sustaining well the lower two-thirds of the abdomen, or from a long and low-reaching corset, fitted and adjusted with the same end in view.

4. The relief obtainable from bandages in any case of movable kidney will depend upon the presence and the degree of any associated enteroptosis. The greater the degree of associated general enteroptosis the better the prospects of relief from a bandage or corset. When movable kidney exists without general enteroptosis, no form of apparatus will prove satisfacory.

5. All forms of apparatus with special kidney pads or trusses are to be absolutely rejected because they are impotent to fix and sustain a movable kidney, and because any pressure they may exercise is injurious to either the kidney or to neighboring organs, especially the vermiform appendix, or to both.

6. In all cases in which relief of symptoms cannot be obtained from either a proper simple bandage or corset, nephropexy is indicated.

Secondary Tuberculosis.—I have repeatedly insisted that in all operations for secondary tuberculosis, complicated by pyogenic infection, it becomes necessary carefully to remove the tuberculous focus and to resort to vigorous means of chemical disinfection so as to render the early removal of the dressing superfluous; that is, iodoform gauze should remain for one or two weeks unless symptoms arise which furnish an indication for its earlier removal.—N. Senn.

VERSION: INDICATION, TECHNIQUE, LIMITATION.[1]

By S. MARX, M.D.,
NEW YORK.

In the performance of version we attempt to substitute one pole of the fœtal plane for another. We recognize but one form of procedure; namely, the true internal version; we admit the value of both the external and the combined varieties, but since there is only an extremely limited field open to both of them it is thought better to limit these remarks to the one variety: the pure internal method. And again I must omit a subclassification of this variety—the various means of manual rectification, which are of great value in their particular sphere. This I do with reluctance, but the time limit in this discussion makes a lengthy discourse on this subject one that is out of the question.

Indications: For purpose of brevity I shall attempt to classify the indications into five categories:

(1) Malpositions and malpresentations.

(2) Contracted pelvis, either relatively or absolutely so.

(3) Prolapsus funis or allied conditions.

(4) For all other unclassified conditions, such as placenta prævia.

(5) Except under very rare conditions, in all cases in which the head remains above the brim; the exception being in those cases in which there is present a uterine rupture or a very much thinned-out lower uterine zone showing plainly the contraction ring of Bandl. This is my only indication for forceps as compared to version when the head is above the brim. But in most of these cases which are prolonged, fruitless, and severe labors, the child has often suffered so severely as to have been already sacrificed, or at best is in imminent danger of dying; here an elective perforation should always be given the preference. Instead of becoming more conservative in the use of destructive measures, in my own work so far as the child is concerned I am frank to admit that there is a very large, useful, and if I may say conservative field in the employment of destructive instruments. I speak from the standpoint of one who wishes to serve the best interests of his patients, and not from the standpoint of the hospital surgeon who is tabulating tables for quantity's, not for quality's sake. My strong plea is for the mother and not for the child when the latter is in extremis. When such conditions obtain and the mother is in danger I invariably sacrifice the fœtus. And it is a rule with me to perforate in all cases in which the child is either dead or is in grave danger, no matter what its position in the pelvis, unless its delivery can be so easily accomplished that the mother runs not the slightest danger by more conservative measures. I wish to emphasize the fact that, with the exception noted above, I stand squarely for an elective version in all cases in which the head remains above the brim; and my reasons for so doing are as follows:[2] Non-engagement of the head means either a malposition of the presenting part, or we are dealing with a pelvis that is relatively or absolutely contracted; and by a relative contraction I mean a pelvis that is large enough to admit of the passage of an ordinary-sized child, yet is too small to admit of the engagement of an overgrown or large-sized head. In this country minor pelvic contractions are not uncommon, and they cause most frequent trouble because of their not being recognized. In these cases the mechanism is different from that which takes place in normal pelves. Instead of engaging obliquely with fair flexion they engage transversely in a condition of hyper-flexion. Since most

[1] Being part of a symposium read before the section on obstetrics, New York Academy of Medicine, April 25, 1901.

[2] Medical Record, April 15, 1899.

contractions are antero-posterior ones with compensatory increase in the transverse diameters, it would appear that nature conforms with what would be an ideal attempt on her part to overcome the dystocia. This is fulfilled in most cases; but in some, at the critical moments, the forces of nature are exhausted and the woman fails to deliver herself. Now if the forceps is applied either from side to side or even obliquely, pressure is exerted more or less from side to side, which in my experience is not compensated for by an overlapping of the bones; and thus, were this true, would not increase the biparietal diameter of the head; but from a personal experience the pressure from side to side causes an increase in the biparietal diameter, which conforms to the contracted antero-posterior diameter of the pelvic inlet. In this fashion it increases the pelvic contraction both relatively and absolutely in this direction. But when version is done under the above conditions, the after-coming head descending as it should be compelled to in a proper mechanism, that is transversely, pressure is exercised by the antero-posterior contraction upon the biparietal bosses, diminishing their diameter where the greatest contraction is; and thus we obtain a compensatory side-to-side head enlargement, which conforms to the enlarged transverse pelvic inlet. This, I believe, explains the superiority and safety for the child of version over the true high forceps application in case of pelvic contraction. And for all these reasons do I elect version over forceps in all cases in which the head remains above the brim. In cases of malpresentations and positions we are again called upon to elect the operation which will most clearly best serve our purpose. All positions, good or bad, which persistently remain above the brim and which are not readily correctible by various measures, should call for an elective version; for instance, posterior occiputs or face cases. When flexion or extension or postural treatment fails, an early and timely version done before exhaustion threatens both mother and child will give us the very best results.

In transverse arm or other atypical positions a spontaneous evolution can hardly be relied upon to overcome the complication. Here I have found that a prophylactic version, done as soon as the membranes have ruptured, serves the best purpose, allowing the active extraction interference to be postponed either until there is an urgent indications to terminate the labor or until the os uteri is fully dilated. More pressing is the indication to interfere when a placenta prævia is evidenced by active hemorrhage or when we are brought face to face with a condition which immediately threatens the life of the child, such as a prolapsed cord. Here an immediate version, preceded or not by a manual dilatation of the os as the experience of the operator dictates, is urgently indicated to alleviate the dangers which immediately threaten either the mother or the child. Other measures which have been recommended for the same purpose are at best uncertain and not to be relied upon; such as in case of a prolapsed cord its replacement by catheter or posture, or in the case of a vicious placental insertion a simple cervico-vaginal tamponade.

Finally, it may be stated in general terms that version is indicated in all cases in which the life of the mother is threatened, as for example by a uræmic convulsion or an embolus of the lung. Under these conditions we must presuppose a dilatable os or one that is fully dilated. When the latter conditions do not obtain we must immediately anticipate the version by a rapid manual dilatation or a deep Dührssen's incision of the os.

Technique: In speaking of the technique of version I shall limit my remarks to the pure internal podalic method. Before going into the details of this operation I beg leave to call your attention to the following rules which have been of inestimable value to me in the past:

(1) Always be sure of the position and the presentation.

(2) Certify to the fact that the fœtus is alive or at best is not in immediate grave danger. If this cannot be done by the ordinary methods introduce the hand in utero and palpate the cord. Unless the child be in such condition that an easy and rapid delivery will produce a living child, it would be far better to do an elective perforation than to subject the mother to any other operation which carries with it an increased danger, for the sole purpose of delivering her of a child that will probably be still-born, or if born asphyxiated will give to this already overcrowded class of idiots another victim in the ranks. We, as accoucheurs, do not follow up these poor unfortunates, but the neurologists and baby doctors can tell us many a sad tale which, as they state, are the result of our too great conservatism in the use of destructive instruments.

(3) Do your version as early as you can in the presence of an intact fruit sac; or, at least, as soon after the membranes have ruptured as possible.

(4) Always introduce the hand corresponding to the position of the fœtal feet.

(5) Always turn the child in such a fashion that will keep nature's classic ovoid intact; that is, carry the foot along the abdominal plane of the fœtus and not away from it. In the presence of unruptured waters it is advisable to preserve the integrity of the membranes until the foot is grasped. The woman being placed on the back, that hand is introduced which corresponds to the position of the feet: the left hand when the feet are in the right segment of the uterus, consequently to the left of the operator as he faces the patient; or the right hand when the opposite condition obtains. Slowly insinuating the hand between the membranes and the uterine wall, it is carried up to the fundus until a foot is felt. It is perfectly immaterial which foot you grasp or whether one or both, so long as you have a foot. If a hand or arm is delivered by mistake, it should not be replaced, but should be left delivered by attaching it to a sling, since I have always felt that an arm delivered is worth two undelivered. Rapidly bringing the foot down in a direction which does not disturb the well-flexed position of the child it is generally advised to finish the case by an immediate extraction. When a manual dilatation has preceded the version it is a well-known clinical fact that a rapid retraction of the lower uterine zone is likely to recur, and for this reason, in order to prevent the head from being caught in the grasp of the spasmodically contracted cervix and causing the loss of the fœtus at the critical moment, it is always advisable to do a very rapid delivery. When we are dealing with a small pelvis the after-coming head must always be guided through the largest diameter of the inlet, which is usually the transverse. As the head comes through the contracted pelvic inlet the woman must be thrown momentarily into the Walcher position in order to increase the conjugate of the inlet, which it certainly does by one-half to three-quarters of an inch, but at the expense of the corresponding diameter at the outlet. Consequently, as soon as the head has passed the contracted inlet the patient must be placed in the exaggerated lithotomy position. I feel that the great error committed by all of us is to rely too much, in delivering the breech, upon the traction efforts instituted by pulling on the legs, and far too little on the vis a tergo. From my own standpoint I always refrain from active traction efforts from below, but use the legs more as a guide for the after-coming head. Well-marked and well-directed pressure from above will do more to keep the head firmly flexed and carry it through the brim than any manœuvre that I know of. The after-

coming head can be delivered by any of the usual methods, but as an accessory measure I have found very useful the introduction of the fingers, not at the point of the jaw but well back to and beyond the root of the tongue, in order more forcibly to flex the head. The malar bones for this same purpose give too little and too uncertain a purchase.

Now as to the limitations of the operation. I feel that I am approaching a very difficult and uncertain theme, for much depends on the skill and the personal equation of the operator in placing the limits of version. If we knew what constitutes a contracted pelvis or if by any known scientific means we could gauge the size of the child's head, we would be dealing with a very simple problem. But no one can have the skill to do this with certainty, but only approximately. For we all have known small babies to be born quickly through markedly small pelves, while on the other hand finely built women have been subjected to grave measures in order to confine them of a very large child. For general purposes, in order to obtain a reasonable working basis, we must estimate from the standpoint of the average pelvis and the average-size child. In all such conditions in which the head remains above the brim a version ought always to be performed, providing the head cannot be pushed into the pelvis by suprapubic pressure. Further, no operative measure short of a perforation should be instituted in the presence of a dead or dying fœtus. Our lowest limit for a deliberate elective version would be in the case of a pelvis whose true conjugate is at or above three and three-fourths inches in the presence of an average-sized or small child. Further, if it be remembered that by placing the woman in the exaggerated extension or Walcher position we obtain an increase of the true conjugate of the inlet of between one-half to three-quarters of an inch, then our extreme lowest limit would be almost three inches. It is of the utmost importance to remember that the time for the Walcher is then and then only when the head is passing the contracted inlet. These measurements are purely arbitrary and certainly would not hold good in the presence of a large or over-sized child. Here then is the time when the matter of personal equation comes in. It has never appeared to me that the subject could be a matter of centimetres or of inches, but a relation, pure and simple, between the ability of the head to pass through the pelvis by head-first or head-last mechanism, or again such disproportion between the two that nothing short of a Cæsarean or symphyseotomy operation would suffice to terminate the labor. Finally the finer details will ever remain a problem which only the individual skill and experience of the expert accoucheur may possibly solve. But this much I may be allowed to opine—and a personal statement it is—and that is, that the operation of version stands squarely midway as an alternate operation between (of course excluding perforation) forceps and Cæsarean section. From what I know my experience has taught me, I feel that the field for symphyseotomy is becoming smaller and smaller, and with increasing expertness in the field of a rational pelvimetry and with the possible hope that our methods for gauging the size of the head of the unborn child will become a finer and more exact art, it is to be hoped that the operation of symphyseotomy will soon be remembered as one that was performed during a wave of an enthusiastic period.

Eucaine hydrochlorate may be combined with two-per-cent. sodium sulphate for subcutaneous injection. For application to mucous membranes when local ischæmia is desired it should be followed or combined with suprarenal extract.—Wingrave.

AXIS-TRACTION FORCEPS.[1]

By EGBERT H. GRANDIN, M.D.,

New York.

The impression I have gained from observation and reading is that but few teachers of obstetrics, and in consequence but few practitioners trained by these teachers, realize the decided advantages possessed, under certain conditions, by the axis-traction forceps over the more familiar type of instrument. It is a surprising matter to me that in this country so little has been written upon the subject of axis-traction, in view of the fact that "fads" (if you will pardon the term) of foreign origin too readily gain entrance here, and that in no country on the face of the globe is the medical profession so prone to test faithfully and to sift judiciously the value of any and every procedure or instrument which is born with or without the weight of authority. Certainly in matters obstetrical we have not moved slowly in almost every respect, and yet to-day, even as twenty-five years ago, the axis-traction forceps, outside of the hands of an exceeding few, is rarely owned and rarely utilized. Has it, therefore, real value?

In 1879 it was my privilege for a few months to walk the wards at the Maternité in Paris with the late Professor Tarnier, and over and again, with the enthusiasm characteristic of his nature, he dilated on and demonstrated the value of axis traction. These views were utterly at variance with those of my teachers in obstetrics—Buckingham and John Reynolds—and I recall the quandary I was in at the outset of my career as to whether it was worth my while to purchase the axis-traction forceps. During my connection with the New York Maternity Hospital and the New York Infant Asylum ample opportunity for practical test offered, with the result that, under the indications I shall shortly dwell upon, I became convinced, and I am still convinced, that the axis-traction forceps is not alone a life-saving measure when any other type of instrument is very liable to fail, but that it also saves fœtal life, with less liability to cause intracranial lesions or to inflict deep and serious damage on the maternal parts.

Before stating tersely the advantages carried by the type of forceps under discussion, it seems wise to recall the following elementary data: The main use of the forceps is as a tractor. Its subsidiary uses are for the purpose of leverage and rotation. Necessarily associated with traction, leverage, and rotation is compressive force applied to the part of the fœtus which is in the grasp of the instrument. Leverage is a necessary accompaniment of traction, for the simple reason that it is infinitely difficult to pull in a straight line. The forceps, as a rotator pure and simple, should rarely be utilized, except in so far as during traction the instrument obeys the natural forces which demand rotation in the given case. Forcible rotation risks deep lesion of the maternal parts, and, furthermore, the fœtal trunk may not follow the movement imparted to the fœtal head, and the result is self-evident.

Forceps application is conveniently divided into high (*e.g.*, the presenting part is above the pelvic brim or engaged by its greater segment); median (*e.g.*, the presenting part is within the pelvic cavity); low (*e.g.*, the presenting part is on the pelvic floor and at the outlet). For the purpose of low application any type of forceps should answer, and similarly in the case of median application in instances in which deficiency in the expelling force is at the bottom of the retardation in labor. High application in my hands is limited to instances in which the membranes have ruptured and the presenting part has just engaged; otherwise, for reasons

[1] Read before the section on obstetrics and gynæcology of the New York Academy of Medicine, April 25, 1901.

which it is beyond the scope of my subject to dwell upon, version should be the operation of choice.

For high application and for difficult median application we need a type of instrument which will fulfil the following indications:

1. Traction in the correct axis.
2. Traction with expenditure of the least effort on the part of the operator.
3. Traction with the least compression of the fœtal head.
4. Traction with the least interference with normal mechanism (*e.g.*, rotation).
5. Traction with least consequent damage to the maternal parts.

Those who are familiar with the axis-traction forceps will tell you that there is no type of the instrument which meets these indications to better advantage.

The first indication is self-evident and requires scarcely any comment. Under the conditions given (high and median application), the necessity for traction downward and backward as much as possible exists, and the axis-traction forceps can alone do this.

The second indication—least effort on the part of the operator—is a necessary corollary to the first indication. The nearer we can approximate traction in the correct axis with the greater facility may the presenting part enter the superior strait and traverse the cavity, and therefore the less traction force requisite.

The third indication—as little compression of the fœtal head as possible—requires some comment. The subject of intracranial lesions and remote effects the result of undue compression during difficult labor, has been dwelt upon so much that I need only refer to it. As practical obstetricians, we must avoid this compression, and in so far as traction is made in the correct axis, compression is certainly lessened. Furthermore, when the fœtal head is properly grasped by the axis-traction forceps it is maintained in position by the contact of the blades of the forceps and the pelvic wall. Extra compression can alone be applied through the screw which the forceps carries, and this screw need rarely be utilized when the operator becomes expert, unless disproportion between the pelvis and the presenting part is so great that delivery by forceps is an impossible problem. Very different is the case with any other type of forceps, in which compression during vigorous traction depends, so to speak, on the strength of the grasp of the operator. The harder he pulls the more firm the grasp.

The fourth indication—non-interference with normal mechanism, *e.g.*, rotation—is alone satisfied by the axis-traction instrument. Imagine the fœtal head grasped by the ordinary type of forceps—and remembering I have always in mind difficult delivery—during vigorous traction the head endeavors to rotate, and the operator cannot—as he should—be conscious of this effort to undergo normal mechanism, it may be, into faulty position, *e.g.*, posterior. Imagine the same head grasped by the traction forceps; the handles of the forceps are an ever constant index of the position the presenting part is assuming, and it is the duty of the traction rod to follow this index. Should the handles turn in the direction which indicates that the head is rotating after a normal mechanism, traction on the rod in the correct line may assist this rotation. Should the handles tell us that the head is rotating posteriorly, the alert operator may sometimes prevent this by making traction in an opposite direction, or by grasping handles and traction rod resort to the procedure so well described recently by Dr. Simon Marx under the term rotary axis-traction forceps. In short, for blind traction is substituted sentient traction.

The fifth and last indication—avoidance of deep lesion to the maternal parts—follows as a corollary from the fact that traction is possible more approximately in the correct axis, and, furthermore, in that the tendency to utilize leverage is reduced to the minimum where the traction rod exists. The "see-saw" motion, which is almost inevitably resorted to when difficult traction is made with the ordinary type of forceps, does not enter into the problem when the axis-traction instrument is substituted.

The rules governing the application of the axis-traction forceps are similar to those associated with other types. In high application the blades are applied to the sides of the pelvis; in median application, to the sides of the fœtal head.

While axis-traction forceps, even as any other type, may slip if improperly applied or if the grasp be faulty—and here the operator is at fault and not the instrument—it must be stringently taught to all who use the former that inattention to the following cardinal rule will always result in slipping, with consequent lesion of the maternal parts. While making traction, the traction rod must ever remain parallel to and almost in contact with the handles. Neglect or ignorance of this rule renders the axis-traction forceps a very dangerous instrument.

Necessarily, within the time limit, I have been unable to enter into details, and have been obliged to be somewhat dogmatic in my statement. My faith is strong, however, that one need only be trained in the use of the axis-traction forceps to learn the wisdom of all I have here written, and then in the hands of the many there will be fewer impossible forceps deliveries, far less avoidable damage to the maternal parts, and—possibly chiefest of all—fewer intracranial injuries laid to the door of one of the most useful and beneficent instruments ever devised.

36 East Fifty-eighth Street.

CÆSAREAN SECTION.[1]

By EDWIN B. CRAGIN, M.D.,

NEW YORK.

For a clear idea of Cæsarean section as it stands today, one has very largely to free himself from past impressions of indications and results and study the operation under the light of present experience.

Into the literature of the subject the writer will not enter, the object of this paper being the presentation of the work in this line done by him at the Sloane Maternity Hospital, and a discussion of the experience gained therefrom. During the last three years the writer has performed Cæsarean section at the Sloane Hospital in nine cases, with a successful result for mother and child in all save one case of advanced carcinoma of the uterus and vagina, in which the child was dead and beginning to macerate, and the operation of Cæsarean section was determined upon not from choice but as the only means of delivering the woman, who evidently had but a short time to live. A brief abstract of the cases is here presented.

Case I.—Mrs. G——, aged twenty-seven years, primigravida, native of Ireland, was admitted to the Sloane Hospital May 31, 1898. Four years previously a ventrofixation had been performed for retroversion of the uterus. Her last menstruation began August 4, 1897. The presentation was transverse; the position, R.D.A. The first stage of labor began May 30th. The membranes ruptured before admission. The abdomen showed the cicatrix of the previous median incision, from which union was apparently not primary. The cervix was situated high up posteriorly and admitted two fingers. Extending from the cervix to the point

[1] Read before the section on obstetrics and gynæcology at the New York Academy of Medicine, April 25, 1901.

of suture of the uterus to the anterior abdominal wall was a muscular tumor, formed of the anterior uterine wall, blocking the entrance to the pelvis. Delivery *per vias naturales* was evidently impossible, and Cæsarean section was decided upon. The Sänger-Cæsarean operation was performed May 31st, the child being delivered in two and one-half minutes from the first incision. The time of the complete operation was fifty-four and one-half minutes. The child at birth weighed eight pounds. The convalescence of the mother was uneventful. She was allowed up on the twenty-first day, and mother and child were discharged in good condition July 6, 1898.

Case II.—Mrs. F——, aged twenty-seven years, primigravida, native of Ireland, was admitted to the Sloane Hospital October 30, 1898. Her last menstruation began January 25, 1898, and lasted only one day, although usually lasting five days. Pelvimetry showed the distance between the spines 23.50 cm.; between the crests, 24.50 cm.; the right oblique diameter, 20.50 cm.; the left oblique, 20 cm.; the external conjugate, 17.75 cm.; the diagonal conjugate, 9.25 cm.; the true conjugate, 7.75 cm. The presentation was vertex; the position, L.O. The fœtal heart beat was 140. The head lay three fingers' breadths above and projecting in front of the symphysis. The membranes ruptured November 4th, at 4 A.M., five days after admission. On November 9th the fœtus showed signs of compression, the fœtal heart slowing down to 60 and an umbilical souffle being detected. The cervix admitted a finger tip. The head failed to descend, and Cæsarean section was decided upon and the Sänger operation performed. The child was delivered in sixty-five seconds from the first incision. The time of the complete operation was twenty-six minutes. Convalescence was interrupted on the sixth day by a rise of temperature to 102.6° and pulse to 156. Vaginal examination showed the cervix contracted and the lochia retained. Temperature and pulse fell to normal on the eighth day, and further convalescence was uneventful. The patient was allowed up on the twenty-first day, and mother and child were discharged in good condition December 15, 1898. The child at birth weighed seven and three-fourths pounds. The diameters of the fœtal head were: suboccipito-bregmatic, 9.50 cm.; suboccipito-frontal, 11 cm.; occipito-frontal, 11.25 cm.; occipito-mental, 13.50 cm.; biparietal, 8.50 cm.

Case III.—Miss F——, colored, aged fourteen years, primigravida, native of the United States, was admitted to the Sloane Hospital November 7, 1898. She did not remember the date of her last menstruation, but felt life in July. She had been a weakly child, not walking till three years old. On admission she measured three feet ten inches in height. She was a rachitic dwarf with a marked lordosis; her abdomen was slightly pendulous, and the tibiæ showed an anterior and inward curvature. Pelvimetry showed a flat, rachitic pelvis. Distance between spines, 23 cm.; between crests, 22.75 cm.; right oblique, 16.25 cm.; left oblique, 17 cm.; external conjugate, 14.75 cm.; diagonal conjugate, 6.50 cm.; true conjugate, 5 cm. Cæsarean section was decided upon and December 5th selected as the date. The child was delivered in thirty seconds from the first incision. The placenta and membranes were removed and then a complete abdominal hysterectomy was performed. The child at birth weighed four pounds nine and a half ounces. The diameters of the fœtal head were: suboccipito-bregmatic, 8.50 cm.; suboccipito-frontal, 10.25 cm.; occipito-frontal, 10.75 cm.; occipito-mental, 12 cm.; biparietal, 8.50 cm. The patient made a good convalescence and union was primary. She was allowed up on the twenty-first day, and she and her baby were discharged in good condition January 6, 1899.

Case IV.—Miss B——, aged twenty-nine years, primigravida, native of Germany, was admitted to the Sloane Hospital December 17, 1898. Her last menstruation occurred March 10, 1898. She had been a weakly child, not walking till three years old. She was in the second stage of labor when admitted. The child was in breech presentation and left sacro-anterior position, both feet and the right hand being easily felt. The breech overrode the symphysis. Pelvimetry showed the following diameters: distance between spines, 28 cm.; between crests, 28.50 cm.; right oblique, 20.50 cm.; left oblique, 20.50 cm.; external conjugate, 17 cm.; diagonal conjugate, 9.25 cm.; true conjugate, 7.75 cm. The size of the pelvis compared with the size of the child seemed too small for delivery *per vias naturales*, and Cæsarean section was determined upon and the Sänger operation performed. The child was delivered in sixty seconds from the first incision, the complete operation occupying forty-two minutes. The child at delivery weighed eight pounds eight and a half ounces, with the following cephalic measurements: suboccipito-bregmatic diameter, 10.50 cm.; suboccipito-frontal, 11.75 cm.; occipito-frontal, 12.75 cm.; occipito-mental, 13.50 cm.; biparietal, 10.75 cm. The union was primary. The patient was allowed up on the twenty-first day, and mother and baby were discharged in good condition January 19, 1899.

Case V.—Miss H——, aged twenty-two years, primigravida, native of the United States, was admitted to the Sloane Hospital September 4, 1899. At the age of eight years her spine was first noticed to be in condition of kyphosis. This gradually increased till she was fourteen years old. Since then she had been strong and well. On admission she measured four feet four inches in height. There was a very marked kyphosis occupying the whole of the dorsal region, with a compensating lordosis in the lumbar. Pelvimetry showed the distance between spines to be 23.50 cm.; between crests, 26 cm.; right oblique, 19.75 cm.; left oblique, 19.50 cm.; external conjugate, 20 cm.; diagonal conjugate, 11.50 cm.; true conjugate, 10 cm. The vagina was posteriorly placed, the hollow of the sacrum easily felt, the subpubic angle acute. The distance from the tip of the coccyx to the subpubic ligament was 6 cm.; between the tuberosities, 5.50 cm. The child was already too large to pass the pelvic outlet, and Cæsarean section was determined upon and performed October 16, 1899. After an abdominal incision from 2 cm. below the umbilicus to 2 cm. above the symphysis the uterus was incised *in situ*, the child extracted in thirty seconds from the first incision, and the uterus then lifted from the abdomen. This was followed by supra-vaginal hysterectomy. The complete operation consumed forty-two minutes. The child at birth weighed seven pounds four ounces. The cephalic diameters were: suboccipito-bregmatic, 9 cm.; suboccipito-frontal, 10 cm.; occipito-frontal, 11.50 cm.; occipito-mental, 12.25 cm.; biparietal, 10 cm. The convalescence was interrupted by two small stitch-hole abscesses, but the wound was entirely healed on the twenty-seventh day. The patient was allowed up on the thirty-third day, and mother and child were discharged in good condition November 28, 1899.

Case VI.—Mrs. M——, aged thirty years, tertiigravida, native of the United States, was admitted to the Sloane Hospital April 11, 1900. She did not remember the date of her last menstruation, but she felt life in the latter part of November, 1899. Her previous labors had been normal. For the past two years she had been suffering with a progressively increasing metrorrhagia and for a year with a foul discharge, emaciation becoming more and more marked. She had lost thirty pounds. The posterior lip of the cervix, the adjoining vaginal vault, and the right side of the uterus were involved in a cancerous mass reaching as high as the brim of the pelvis. A recent posterior laceration

of the cervix had been produced by traction on the growth by a midwife who mistook it for an extremity. This caused considerable hemorrhage before the patient was admitted to the hospital. On admission the cervix admitted two fingers. The patient's pulse was 88 but small and weak. The fœtal heart could not be heard. The patient was very restless and vomited coffee-ground material. She had been in labor twelve hours and the uterus was in tonic contraction; the pains were severe with no intermission. She was given chloral by the rectum and morphine hypodermically and sent to bed. On the following morning, April 12th, the cervix still admitted only two fingers. The tissue of the lower uterine segment was so infiltrated and rigid that, in spite of the child being already dead, Cæsarean section was determined upon instead of craniotomy. The child, slightly macerated, was extracted in one and one-half minutes from the first incision. Abdominal hysterectomy was then performed. The patient stood the operation poorly, and in spite of liberal stimulation and saline intravenous infusion during and after the operation she gradually failed and died in three hours. The child weighed five pounds fifteen and a half ounces.

Case VII.—Mrs. O——, aged forty-five to fifty, primigravida, native of Bohemia, was admitted to the Sloane Hospital December 17, 1900. She said her age was fifty years; her relatives said she was only forty-five years. Vaginal examination was difficult on account of extreme rigidity of the perineum and obliteration of the vaginal fornices by senile vaginitis. The os uteri was also obliterated. The presentation was vertex; the position L.O.A. The last month of pregnancy was normal save for recurrent attacks of indigestion ascribed to improper mastication of food, her teeth being mostly gone. The first stage of labor began January 26, 1901, at 11 A.M. At 5 P.M., the cervical atresia persisting, an opening was made with the scissors and the cervix dilated under anæsthesia sufficiently to admit a No. 2 Champetier de Ribes bag. The pains continued, and at 1 A.M. January 27th, No. 2 bag was pulled through and a No. 4 inserted. This was removed at 4 P.M. At 10 A.M., no progress having been made, the membranes were ruptured. On the morning of January 28th no progress was found; the cervix was still rigid; the head had not engaged; the uterine pains were diminishing; the fœtal heart was slow, and the mother was becoming exhausted. As the mother was anxious for a living child, Cæsarean section was determined upon and performed at 11:30 A.M. January 28th. After the usual abdominal incision the uterus was incised *in situ*, and the child extracted in twenty-five seconds from the first incision. The uterus was then lifted from the abdomen and the placenta and membranes were removed. The uterine incision exposed a fibroid tumor about the size of an egg. This was excised and the uterine incision was closed by interrupted sutures of catgut, including all layers but the endometrium. Over this line of suture the peritoneum was approximated by a continuous Lembert suture of catgut. The abdominal wall was closed by a continuous catgut suture in separate layers for peritoneum, fascia, and skin; that for the skin being subcuticular. A small umbilical hernial sac was dissected out before the abdomen was closed. On the morning of the third day the patient got out of bed to procure a drink of water, apparently with no ill effects. She was allowed up on the twentieth day, and was discharged with her baby, both in good condition, March 7, 1901.

Case VIII.—Miss S——, aged thirty-one years, primigravida, native of Germany, was admitted to the Sloane Hospital March 25, 1901. She was evidently rachitic in early childhood, not walking till four years old. Her last menstruation occurred June 6, 1900. On admission, the membranes were found ruptured, the fœtal head lying high; the promontory was easily felt. Pelvimetry showed: distance between spines, 26 cm.; crests, 28.50 cm.; right oblique, 22 cm.; left oblique, 21.50 cm.; external conjugate, 19.50 cm.; diagonal conjugate, 9.25 cm.; true conjugate, 7.75 cm. After a careful estimate of the relative size of the head and canal it was decided that delivery of a living child *per vias naturales* was impossible, and Cæsarean section was determined upon and the Sänger operation performed March 26, 1901. The child was delivered in forty-nine seconds from the first incision. The uterine incision was closed as in the preceding case. The urine at the time of operation contained eighty per cent. albumin and her convalescence was complicated by toxæmic symptoms, but these gradually subsided and the patient made an excellent recovery. The child at birth weighed six pounds thirteen ounces. The cephalic diameters were: suboccipito-bregmatic, 9.75 cm.; suboccipito-frontal, 11 cm.; occipito-frontal, 11.75 cm.; occipito-mental, 12.75 cm.; biparietal, 10 cm. The growth and development of the child were all that could be desired.

Case IX.—Miss T——, colored, aged twenty-four years, primigravida, native of the United States, was admitted to the Sloane Hospital April 9, 1901. Her last menstruation occurred August 12, 1900. Her health had been good up to the onset of labor which occurred fourteen hours before admission. She had been under the care of a midwife and a physician, by whom frequent examinations had been made. On admission, the patient was in good condition; the presentation was vertex; the position, R.O.P. The fœtal heart sounds were good. Vaginal examination showed a firm, sausage-shaped tumor lying in the hollow of the sacrum, fixed below the pelvic brim and greatly diminishing the parturient canal. A diagnosis of congenital displaced kidney was made and Cæsarean section determined upon as the safest method of delivery. After manual dilatation of the cervix for drainage, the abdomen was opened by a median incision extending from the umbilicus 10 cm. downward. The uterus was incised *in situ* and the child delivered in twenty-seven and four-fifths seconds from the first incision. The uterus was then lifted from the abdominal cavity, the placenta and membranes were removed, and the uterine incision was closed by three rows of continuous catgut sutures, the endometrium not being included in the suture. Examination showed both kidneys congenitally displaced; the right being firmly attached below the brim of the pelvis, the left loosely attached at the left sacro-iliac synchondrosis, and the two kidneys loosely attached to each other. The convalescence of the patient was complicated by a mild grade of sapræmia due to retained lochia; but after one intra-uterine douche the temperature fell to normal and thereafter remained so. The child at delivery weighed five pounds fourteen ounces. It was not a vigorous child and lived for only two weeks. The mother was suffering from albuminuria at the time of her delivery, which may have accounted for the low vitality of the child.

This series, though not a long one, seems extensive enough, and with indications for operation varied enough to enable one to gain a just opinion of the procedure, its indications, results, and methods. With the development of the science of obstetrics, the more careful study of each individual case from early pregnancy till the close of the puerperium, and the improvement in the technique and results of cutting operations for the delivery of the living child, the conclusion is being gradually established among the profession that a deliberate craniotomy, or embryotomy upon a living child, with the mother in good condition, is justifiable only in conditions of emergency and ex-

treme infrequency. The writer frankly admits that in private practice the obstetric surgeon has to be governed very largely by the wishes of the family and friends of the patient, who may induce him to attempt an obstetric operation which, although not offering so great a chance of saving the life of the child, does avoid a cutting operation upon the mother. Many craniotomies have been done only as a last resort after an attempt at version or a prolonged forceps operation has failed, the life of the child having in the mean time probably been sacrificed.

A certain number of these cases will probably always occur, as with the difficulty in determining the relative size of passenger and passage mistakes are bound to occur, and heads too large to pass unreduced in size through a given pelvic canal will escape the knowledge of the surgeon until too late to deliver by any other procedure than that of reduction in size of the presenting part.

Such an occurrence, however, should be a rare one, and with increasing study and knowledge of the relative size of child and canal, and resort to the induction of premature labor at the proper time, it will be still more rare. The question of prime importance in determining to recommend and perform one of the cutting operations upon the mother in order to save the life of the child is this, What is the danger to the mother? The writer believes firmly in the rule that in all procedures in the conduct of a parturition the life of the mother stands first, and if either life has to be sacrificed it should be that of the unborn child. So long, then, as the maternal mortality of the cutting operations varied in different countries from fifty to ninety-nine per cent., as obtained twenty-five to thirty years ago, no conscientious surgeon could feel justified in advising these procedures, especially in private practice, if delivery of the woman in any other way was possible. With a maternal mortality below ten per cent., however, as shown by the statistics of Leopold, Olshausen, Reynolds, and others, one must consider, in certain cases at least, the question of fœtal as well as maternal life. It must be admitted that there is and should be a freer field for obstetric surgery in hospital than in private practice, for reasons of greater control of patients, more favorable surroundings, ease of preparation for operation, and abundance of assistants. It is in hospital practice, then, that we will first discuss the maternal mortality of cutting operations for the delivery of living children. Have we reached a point in the development of obstetric surgery when in a modern hospital, with a woman in good condition, we are justified in delivering that woman by a cutting operation when we are convinced that the life of the child can be saved in no other way? The experience of the writer with the nine cases here reported seems to justify him in an affirmative answer. Case VI., with carcinoma, the only fatal one in the list, can hardly be used in the general discussion of the subject, as here the indication for Cæsarean section was absolute and choice found no place, as it seemed to the writer that craniotomy would be impossible without losing the patient on the table from laceration and hemorrhage. The smooth recovery of the eight remaining mothers and the life of the eight children left no doubt in the writer's mind that delivery by a cutting operation in hospital cases, when by such a procedure alone could a living child be secured, was not only justifiable but the only right course. There are two periods when the question of delivery by a cutting operation presents itself for acceptance or rejection:

1. Early in pregnancy when a prognosis of a difficult or obstructed labor is made.

2. In labor, difficult or obstructed.

In early or mid pregnancy, if the case is seen to be one to give marked difficulty in delivery, the question of a cutting operation upon the mother comes in competition with the induction of premature labor and as a rule yields to it as the operation of choice, except in cases in which the delivery of a viable child by this latter procedure seems impossible. At the time of labor several questions present themselves:

1. Can the woman be delivered of a living child by forceps or version?

2. Is the woman in good condition?

3. Is the child in good condition?

If the woman can be delivered of a living child by forceps or version, the question of a cutting operation should not present itself. If the woman cannot be delivered of a living child by the above milder obstetric procedure, the question of a cutting operation comes in competition with a craniotomy or embryotomy.

If the woman is in poor condition, so that her life would be seriously endangered by a cutting operation upon her, such a procedure should, in the judgment of the writer, yield to a craniotomy be the child living or dead.

If the child is in poor condition and its chance of survival slight, all cutting operations upon the mother should yield to a craniotomy, unless the parturient canal is so obstructed that delivery by craniotomy would expose the woman to greater dangers than Cæsarean section.

With the woman and child both in good condition and delivery by version or forceps impossible (determined perhaps by a gentle application of and traction by the forceps), the question of a cutting operation presents itself with especial force. Although formerly in competition here with craniotomy, the writer believes that, for hospital practice at least, that time has passed, and the time has come for the latter to yield to the former; for the cutting operation upon the mother in the interest of a living child to take its place as the recognized procedure, justified and expected. Having decided that a cutting operation for the delivery of a living child is indicated, which shall it be? At the present day there are only two which claim or deserve consideration—Cæsarean section and symphyseotomy. In extreme degrees of pelvic contraction there is no competition between the two operations, and with a true conjugate of 6.5 cm. or less we are all agreed that if a living child is to be delivered it must be by Cæsarean section. Personally the writer never wishes to attempt the operation of symphyseotomy with a true conjugate below 7 cm. In cases in which the parturient canal is obstructed by tumors either uterine or ovarian, and in obliquely contracted pelvis with an ankylosis of one or both sacro-iliac synchondroses, we are generally agreed that symphyseotomy is not indicated. It is then only in cases with a true conjugate between 6.5 cm. (better 7 cm.) and 9 cm. that symphyseotomy comes in competition with Cæsarean section. On this common ground which operation deserves the preference of the surgeon? In choosing an operation for a patient under his care the surgeon should be influenced by the following factors: 1, the mortality of the operation; 2, the ease and rapidity of convalescence; 3, the ease of the surgeon.

In both the operations under discussion there are two patients for whom the mortality must be considered. It is a difficult matter to arrive at a just conclusion regarding the mortality of the two operations. Francourt Barnes, in a paper before the International Congress at Amsterdam in 1899, gives for—

Symphyseotomy: Maternal mortality, 10.8 per cent.
Fœtal mortality, 14.5 per cent.
Cæsarean section: Maternal mortality, 7.6 per cent.
Fœtal mortality, 7.6 per cent.

While the advocates of symphyseotomy may claim that in similar cases the above statistics are unjustly adverse to symphyseotomy, it is generally agreed that

the maternal mortality from symphyseotomy is as high as and the fœtal mortality higher than from Cæsarean section. While the writer has been fortunate in securing living children in the symphyseotomies performed by him, he has lost one mother whom he has always felt Cæsarean section would have saved. So far, then, as mortality of mother and child is concerned, symphyseotomy has nothing to recommend it over Cæsarean section. Regarding the ease and rapidity of convalescence, the writer believes that no one who has watched the convalescence of patients after the two operations would fail to select Cæsarean section if given the choice.

The ease of the surgeon during any operation depends chiefly on whether he has during the procedure each step of the operation thoroughly under his control.

Here it is that Cæsarean section has a distinct advantage over symphyseotomy. The one object of the operation is the delivery of a living child, yet there must exist in every symphyseotomy a doubt in the mind of the operator as to whether the space gained will enable him to save the child. When one compares this doubt with the comparative certainty that, if the child is in good condition when a Cæsarean section is begun, that child will be saved, few surgeons will hesitate on the ground of their own ease to choose Cæsarean section.

Viewed from the standpoint, then, of mortality, ease and rapidity of convalescence, and ease of the surgeon, Cæsarean section deserves the preference even in the class of cases in which symphyseotomy comes in distinct competition with it, and if this decision is justified in hospital practice, much more does it hold in private practice, in which certainty in result and ease of convalescence are the chief demands.

The writer will, perhaps, be criticised for attempting the rôle of a prophet; but after a careful study of the operation during the last three years, watching patients convalesce from a Cæsarean section with the same ease as from a salpingo-oöphorectomy for diseased appendages, or an abdominal hysterectomy for fibromyomata, he cannot but feel that the time is not far distant when in private practice patients with parturient canals so contracted as to make delivery possible only with marked danger alike to themselves and their children, will be prepared for and subjected to Cæsarean section with satisfaction to themselves and their friends.

A few points in the technique of the operation deserve consideration. If there is one condition which above others conduces to the comfort of the patient after operation, it is an empty alimentary canal when the patient is placed upon the table, as otherwise the pressure of the large uterus in a contracted pelvis soon compresses the rectum sufficiently to cause distention and discomfort.

In the first four operations of the series the uterus was lifted through the abdominal wound before the uterine incision. The length of the abdominal incision required for this procedure induced the writer in the fifth and subsequent cases to incise the uterus *in situ* and deliver the child before raising the uterus out of the abdominal wound. Pressure of the abdominal walls against the uterus by the hands of an assistant during the extraction of the child prevents soiling of the peritoneum, and the shortness of the abdominal wound and resulting cicatrix justify the method.

During all the operations the broad ligaments were held by the hands of an assistant, and contraction of the uterus was stimulated by frequent irrigation with hot saline solution.

In the first six cases, in which the uterus was not removed, the uterine wound was sutured with one row of interrupted silk sutures passing through peritoneum and muscle, but not including the endometrium. Over this line of sutures the peritoneum was approximated by a continuous Lembert suture of catgut.

In the last three cases the uterine wound has been sutured entirely with catgut, in the first two of these three cases catgut being substituted for the deep interrupted sutures of silk, and in the last case three rows of continuous catgut suture being used. The results with the use of catgut have been so satisfactory that the writer feels justified in discarding the silk suture. While in the early cases the abdominal incision was closed with through-and-through sutures of silkworm gut, the fascia being approximated by a continuous suture of catgut, in the last three cases the abdominal wound was closed by continuous catgut suture in separate layers for peritoneum, fascia, and skin, that for the skin being subcuticular. This last method of suture has proven most satisfactory.

Some operators advise placing the omentum behind the uterus before closing the abdominal wall, so that if leakage should occur from the uterine cavity it would find its way through the abdominal wound to which the uterus had become adherent. The writer believes this not only unnecessary but detrimental, and prefers to avoid adhesion of the uterus to the abdominal wall as much as possible by drawing the omentum down in front of the uterus and over its incision. The tardy involution of the uterus and tenderness of the fundus, observed in some cases, are undoubtedly due to adhesion between the uterus and the abdominal wall.

The tendency of the cervix to contract and involute more rapidly than the body of the uterus, and the consequent danger from retention of the lochia, emphasize the importance of a manual dilatation of the cervix if dilatation by the bag of waters or the presenting part has not taken place.

Regarding the performance of an hysterectomy as a succeeding step to Cæsarean section opinions differ. Following in the line of recent conservative work in gynæcology, and realizing that, as a general rule, a woman is healthier and happier in the possession of all her organs, the writer has thus far adopted the plan of leaving the uterus, if it and the appendages are normal, and there is a possibility of the delivery of a living child without a cutting operation if labor is induced even as early as at seven months.

If the uterus or appendages are infected or diseased, or the pelvic deformity is extreme, the writer prefers to follow the Cæsarean section by hysterectomy.

62 West Fiftieth Street.

A Case of Papillomatous Cyst in a Child Four Years and Nine Months Old.—Manning Simons reports this case. On examination the child's abdomen was found very much distended. It was full of fluid with a solid mass most prominent at the umbilical region and extending toward the right side. Its outlines were difficult to distinguish, and its connections could not be traced, on account of the great distention and tension of the abdomen. At operation the tumor was found to be attached by a thin pedicle to the right lateral wall of the pelvis. The pathological report was as follows: This tumor belongs to the variety known as the teratomata. These tumors are usually cystic in nature, congenital, and very complex as to their histological structure. This one is probably congenital, and takes its origin from the ovary and broad ligament. Histologically, it consists of papillomatous cysts containing mucoid material; the stroma is mixed, both adult and embryonic tissue being present, also bundles of unstriped muscle, and plates of cartilage. This stroma at certain places looks decidedly sarcomatous. The tumor is probably malignant

and apt to recur. The child is at present, however, apparently in the best of health.—*Virginia Medical Semi-Monthly*, March 22, 1901.

Some Anatomical Lesions Caused by Tuberculous Poisons.—Angelo Marcantonio has found that the defibrinated blood of animals suffering from experimental acute miliary tuberculosis, when injected after filtration into the peritoneum or the subcutaneous connective tissue of healthy animals, causes the formation of tuberculous-like foci in lungs, liver, and spleen, but without bacilli or giant cells. The substance of the body of the tubercle bacillus, which is insoluble in chloroform, injected into the veins of a rabbit causes the formation of giant cells scattered throughout the tissues of the lungs, liver, and spleen. When injected subcutaneously or in the peritoneum it causes small abscesses or caseous nodules at the point of injection, besides an extensive destruction of the red blood corpuscles. The other constituent of the bacillus which is soluble in chloroform produces no lesion beyond an induration, sometimes followed by an eschar, at the point of injection.—*Giornale Internazionale delle Scienze Mediche*, March 15, 1901.

Albuminuria in the Early Stages of Syphilis.—C. P. Bacon says that there is no clinical difference between Bright's disease occurring as an accident of secondary syphilis and the malady as usually observed. And, if it were not for the existence of syphilitic lesions and the unhoped-for benefit sometimes obtained from specific treatment, the real nature of the disease would often remain uncertain. As in many cases every sign of syphilitic taint has at this period disappeared, there is little doubt that many cases of this kind have passed unnoticed. Taking into consideration particularly the dyscrasic state of the system in syphilis, the functional derangements and the organic lesions of the urinary apparatus may be attributed to a primary alteration of the blood, particularly of its globules and albuminoid principles. But it might also be affirmed that the micro-organisms of syphilis in their migration through the kidneys may determine a sort of traumatism of the arterial walls and of their cellular elements, and thus induce infectious nephritis.—*Massachusetts Medical Journal*, April, 1901.

Meckel's Diverticulum as a Source of Intestinal Obstruction.—J. F. Purviance believes that there can be no reasonable doubt of the fact that many cases of formidable obstruction and intestinal inflammations arise from this source. And yet, in a common way, every other possible cause is thought of before this. If the severity of the case leads to an operation, the search is for appendicitis, intussusception, concretion, torsion, omental hernia, etc., while a little pouch may hang from the ileum so harmless in its appearance as scarcely to attract attention, and yet be responsible for every evil result in the case. It is the writer's belief that the case of a child or an adult with intestinal obstruction and centrally localized pain in connection with early vomiting and hiccough, and with little or no rise of temperature, should justify a diagnosis of diverticulum, so far as to authorize an early incision for exploration. All due efforts should be first made for relief, but no unnecessary time should be lost in this course if benefits are to be expected from an operation.—*Medical Summary*, April, 1901.

Diagnosis between Appendicitis and Typhoid Fever.—M. R. Richardson states that in rare instances an appendicitis in which the abdominal symptoms are mild simulates a typhoid in which they are pronounced. The symptoms which should put the surgeon on his guard against typhoid are, in the order of their importance: pain without rigidity; pain and tenderness without rigidity; pain and tenderness without rigidity, without tumor; a history of malaise, headaches, slight fever preceding the pain, even if of only twenty-four hours' duration; an initial and sustained temperature of 103° or more preceding the pain; increased area of splenic dulness when other symptoms suggest equally appendicitis and typhoid fever; rose spots, and normal leucocyte count. Sometimes the diagnosis cannot be made. It will be almost always safe to wait, and the surgeon should wait when, from the absence of rigidity and tumor, typhoid is suspected, especially if the patient is near at hand. Twenty-four hours will usually be time enough to establish the diagnosis of appendicitis or to rule it out. Many days may be necessary to recognize positively typhoid fever. The dangers of exploration in the initial days of typhoid are probably slight. The wound pursues an aseptic course. In one case, at least, if it existed, the disease was aborted by the removal of the mesenteric glands and the appendix. Moreover, the most experienced and careful diagnostician may be misled by the prominence of abdominal symptoms in typhoid into advising operation. Chagrin at such a mistake should not be felt if the examination has been careful and thorough, with the possibilities of typhoid being kept well in mind. Finally, even with the abdomen opened, there is no positive way of recognizing typhoid in the first days. When glands are removed which present the features of typhoidal glands, a rapid convalescence of the patient throws some doubt upon the diagnosis, especially when no typhoid bacilli are found in the glands and the cultures from blood serum are sterile.—*Providence Medical Journal*, April, 1901.

Epidermolysis Bullosa Hereditaria.—H. L. Smith reports a case of this rare skin disease, claiming that it is the first ever recorded as occurring in the negro race. His patient was a girl of seven who had been subject since early infancy to a breaking out of water-blisters on her hands, feet, buttocks, and scalp. The eruption began as small, itching pimples, which were rapidly transformed into tense vesicles, varying in size from a small pea to a pullet's egg. They remained about one week before breaking, and after drying up left a brownish discoloration but no scar. It had been noticed that these blisters were numerous in the warm weather of spring and summer, and had rarely appeared during the winter. The father, who gave the history, had since his earliest recollection been at times a sufferer from the disorder. His mother was also similarly affected. His wife had never miscarried, and was the mother of eight children, three of whom—two brothers and one sister of the patient—had at intervals since their birth had the eruption. The father remarked that the children who appeared the strongest were those affected. The patient had gone without shoes during the last summer, owing to the fact that they had been during the previous summer a constant source of irritation to her feet, with consequent blister formation. Examination of the patient showed on the scalp, buttocks, abdomen, and the extensor surfaces of the forearms and legs pigmented areas. Tense bullæ, containing clear fluid, and ranging in size from a large pea to a robin's egg, were situated mainly on the feet. On the outer and inner surfaces of the left foot, below the malleoli, were large bullæ. The exudate of the inner bulla was slightly blood-tinged. Behind the right heel there was a bleb of considerable size, which caused the patient to limp. Vesicles of smaller size were irregularly scattered over the feet and the legs. The smallest one was on the extensor surface of the left forearm, just above the wrist joint. Excision of a bleb was refused. When the patient was next seen, two weeks later, all the bullæ had disappeared.—*Maryland Medical Journal*, April, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE PROGRESS OF SANITATION IN HAVANA.

No branch of preventive medicine—if it may be so termed—has made such remarkable advance during the past fifty years as has sanitary science. In those places where our present knowledge of sanitation has been thoroughly applied, the increased healthfulness has seemed to be in many instances almost supernatural; and even when, owing to prejudice or niggardliness, the efforts of the sanitary reformer have not been allowed full sway, decided beneficial effects have always resulted.

A better example of the truth of this latter statement cannot be brought forward than Havana. In the MEDICAL RECORD reference has been often made to the much more favorable hygienic conditions which have followed the introduction to a somewhat limited extent of American methods of sanitation in that city. The report of Major Valery Havard, chief surgeon of the department of Cuba, which has been recently published, strongly emphasizes this fact. However, as statistics of the death rates of Havana for the past ten years, given in the report of Major W. C. Gorgas but a short time ago, were commented upon at length in this journal, there is no need to discuss this phase of the question here. Other points no less instructive in Major Havard's report invite a critical consideration.

In the first part of the report Major Havard examines the special causes to which the high mortality of Havana must be attributed, how they can be remedied, and what has already been done to that end. These causes can be placed under the following headings: Sewerage, street and house sanitation, disposition of garbage, overcrowding and ventilation, clothing, food.

Of this list it is stated that an efficient system of sewerage is the most immediate and pressing necessity, and until this is introduced sanitary methods, however well carried out, must to a great extent fail.

Street and house sanitation has been conducted in a vigorous and successful manner from the beginning with correspondingly successful results. The garbage is now mostly conveyed to the deep sea, and not, as under the Spanish *régime*, dumped into the bay. Nevertheless the bay is still much contaminated by drainage and refuse. Major Havard believes that this means of infection will be completely avoided when all the sewage is carried to the open sea as contemplated, and that the bay will then disinfect itself, rendering unnecessary the proposed canal.

The overcrowding of Havana is, with the defective sewerage system, the most fruitful cause of the propagation and spread of disease in the city. When it is stated that the population of Havana is two hundred and fifty thousand persons, contained in about twenty-six thousand houses, the ill effects to health will be readily believed. Through ignorance and poverty many of the inhabitants are not suitably protected against climatic changes. Much mortality is caused especially among male infants by allowing them to go naked or scantily clad about the house or in the street.

With regard to food, Major Havard is of the opinion, held by a large number of authorities, that meat is an indispensable component of a good diet in all parts of the world, and that to its lack in tropical countries among the poorer dwellers is due their anæmic and generally unhealthy appearance.

The second part of the report will arouse close attention. It deals with yellow fever from the standpoint of the sanitarian.

In these days nothing is more typical of the age than the overthrowing of old, long-cherished beliefs and theories; this is especially the case in matters pertaining to medical science. This iconoclastic spirit is excellent when not carried to excess, and is the road which leads to true progress. The time-honored theory as to the etiology of yellow fever has been the last to be shattered. Yellow fever has ever been esteemed a disease having its origin principally in filth; in fact, unsavory surroundings have been looked upon as indispensable to its inception and spread. The investigations of Major Walter Reed and his co-workers have demonstrated with apparent certainty the fallacy of this theory, their researches having shown that yellow fever is propagated in the identical way by which malaria is communicated, and that fomites and contagion have nothing to do with the case.

Major Havard, arguing from his experience in Havana, is a strenuous supporter of these views, and points out that in Havana in 1900 no visible correlation could be seen between dirt and yellow fever, the district which became first strongly infected being one of the cleanest and best constructed, while the most unsanitary wards became infected late in the season, and only to a slight extent. Hygienic conditions did not influence in any degree the direction of the fever; it did not follow the poor and unclean, nor the march of previous infections, but rather the movements of non-immunes. The discovery that mosquitos are the chief if not the only means of conveying yellow fever, should be of inestimable value. Indeed, Major Havard is sanguine enough to anticipate the total eradication of both yellow fever and malaria from Havana by the destruction of the malaria-bearing Anopheles and that of the yellow-fever-bearing Culex. While not doubting that the extirpation of the insects in question would have a remarkable effect in the subjugation of the two diseases, attention may be drawn to the fact that the problem of how wholly to destroy these mosquitos has yet to be solved, and is, more-

over, one which on an extended and a comprehensive scale would seem to present almost insuperable difficulties. Preventive measures, such as the careful protection of patients and non-immunes by mosquito-nets, the isolation of those infected, and, above all, the thorough drainage of the vicinity, should go far toward ridding Havana of the yellow-fever pest.

There is also another important lesson to be learned from the discovery of Major Reed and his colleagues—that infected linen, bedding, and effects of all kinds play no part in the conveyance of the malady. The existing methods of disinfection and quarantine must be revolutionized. Disinfection is useless when there are no infectious germs to destroy, and consequently the object to be attained is simply to find out the most effective methods of destroying infected mosquitos which lurk in the house in which patients are cared for. Major Havard recommends formaldehyde gas for this purpose. Again, with regard to quarantine, upon the assumption that infectious germs do not exist outside of man and the mosquito, disinfection of baggage is as a natural sequence superfluous. Detention of possibly infected persons for five days and fumigation of the ship with formaldehyde will be, as in the case of a dwelling, an effectual safeguard against the spread of yellow fever.

Given that yellow fever is propagated solely by the agency of the Culex as the intermediary host, it is clearly obvious that the destruction of and protection from infected mosquitos must be the preventive measures employed.

Major Havard concludes his report by discussing the question of immigration as a means of keeping alive yellow fever in Havana, and discourses instructively upon the subject of immunity against the disease. His paper is an excellent presentation of the whole situation as regards yellow fever in Havana, and deserves to be widely read.

ANOPHELES AND MALARIA.

The *Journal of Hygiene*, a new British quarterly, produced under the editorship of Dr. George H. F. Nuttall, lecturer in bacteriology and preventive medicine in the University of Cambridge, late associate in hygiene in the Johns Hopkins University, Baltimore, assisted by an able staff, contains among other good things the first instalments of a series of studies in relation to malaria. The first article, contributed by Dr. Nuttall, Dr. Louis Cobbett, and Mr. T. Strangeways-Pigg, treats of the geographical distribution of Anopheles compared with the former prevalence of ague in England, and incidentally goes to show that the assertion of Grassi, to the effect that the geographical distribution of the genus Anopheles coincides with that of malaria, does not hold good in all parts of the world. In his latest publication Grassi, basing his deductions upon the results of his investigations in Italy, makes the claim of this coincidence, and proceeds, on the strength of their wider geographical distribution, to exclude a number of blood-sucking animals from being possible carriers of the parasites of malaria. The observations of MacDonald in Southern Spain would seem also to add greater weight to the contention of Grassi.

The authors of the article in the British *Journal of Hygiene*, while not doubting that the number of Anopheles present in a district will be found to agree with the extent to which malaria prevails, at the same time clearly demonstrate that Grassi's claim has no general application, for they have found Anopheles in many parts of England where there is no record of malaria having previously existed, and where there is certainly no malaria to-day.

After describing the methods of their investigations and the former geographical distribution of ague in Great Britain, the writers end a most interesting article by saying: "It having been incontestably proved in Italy, Holland, England, and the United States that at least two species of Anopheles occurring in Great Britain are capable under certain conditions of transmitting malarial infection to man, we, on the strength of our investigations, have reached the following conclusions:

"1. The disappearance of ague from Great Britain does not depend on the extinction of mosquitos capable of harboring the parasites of malaria.

"2. Three species of Anopheles (A. maculipennis, A. bifurcatus, A. nigripes) are to be found in Great Britain in all districts which were formerly malarious, but also in places concerning which there is no record of the former prevalence of ague.

"3. The Anopheles to-day are most numerous in low-lying land containing many ditches, ponds, and slowly flowing water, suitable for their habitat, and corresponding to the districts where ague was formerly prevalent.

"4. Since the disappearance of ague does not depend upon the extinction of Anopheles, it is probably due to several causes operating together:

"(*a*) A reduction in the number of these insects consequent upon drainage of land, this being in accord with all the older authors, who attributed the disappearance of ague largely to this cause.

"(*b*) Reduction of the population in infected districts as the result of emigration about the time when ague disappeared from England. This would naturally reduce the number of infected individuals, and thus lessen the chance of the Anopheles becoming infected.

"(*c*) It is possible that the use of quinine has reduced the chances of infecting the Anopheles through checking the development of the parasites in the blood of subjects affected with ague.

"Of these the first-mentioned cause seems to have been chiefly operative. The possibility is not yet excluded of there being another intermediary host besides man capable of harboring the parasite, and, assuming that this were so, this host may have become extinct in the lowlands where it is known that the fauna and flora have altered.

"5. The coincidence of the geographical distribution of ague and Anopheles, as claimed by Grassi for Italy, and as probably holding good for other parts of the world, is hereby disproved for England, and conse-

quently the generalizations are proved to be premature whereby he excludes other blood-sucking insects from being possible hosts of malarial parasites on the strength of this supposed geographical agreement.

"6. Since the geographical distribution of Anopheles in England is wider than the former distribution of ague in this country, we are forced to conclude that it is not a matter of the geographical distribution of Anopheles as much as of their numerical distribution.

"7. Our observations having proved the existence of Anopheles in non-malarious districts, we believe they will explain the occasional occurrence of ague in out-of-the-way places, without making it necessary to assume that malaria-bearing mosquitos have been freshly imported, for, given suitable conditions of temperature and the requisite number of Anopheles, a malarious subject coming from other parts might well infect the local insects, which in turn would spread the infection to healthy persons.

"8. We would suggest to those engaged in the investigation of malaria in other countries to search as carefully for Anopheles in non-malarious as in malarious regions. More data as to the number of these insects in various localities are certainly required, though we are fully aware that numerical estimates permit of a considerable degree of error. Nevertheless they would always possess a relative value."

The foregoing summing up, although somewhat lengthy to be included in an editorial, is so suggestive and so much to the point that a thorough understanding of the author's position with regard to the question would be difficult if this were not done.

Of late it has been taken perhaps too much for granted that several species of Anopheles are the only agents in the spread of malaria. Of course Ross, Bignami, and others have made it a matter of common knowledge by means of their brilliant researches that species of this mosquito act as hosts of human malarial parasites, and that when thus infected are capable of communicating the parasite to man, but the investigations above referred to tend to cast some doubt upon the theory that these are the only possible carriers of the parasites of malaria. At any rate the geographical distribution of Anopheles and of malaria, so far as Great Britain is concerned, does not support this view of the case.

The advice, therefore, to search as carefully for Anopheles in non-malarious as in malarious regions is exceedingly apt, and should, if diligently followed, supply all the missing links in the chain of research.

The proposition put forward by Dr. Nuttall and his collaborators, that there may be another intermediary host besides man capable of harboring the parasite, is well worthy of consideration, and would, if proved, explain much that is at present incomprehensible in the problem. The studies of malaria contained in the British *Journal of Hygiene* are valuable contributions to the literature on the subject, and will, we trust, inspire investigators to pursue zealously the same lines of research in other countries.

The number of suicides in New York during the past quarter averaged over two daily.

PLAGUE IN SAN FRANCISCO.

THE report of the special commission appointed by the United States government to ascertain the existence or non-existence of bubonic plague in the State of California, and in the city of San Francisco in particular, was published in the Public Health Reports of April 19th.

The appointment of such a commission was undoubtedly a wise and necessary step on the part of the government, as it has disclosed the exact conditions of affairs to the American public, which by reason of the somewhat conflicting accounts which have appeared from time to time, within the past twelve months, has not clearly understood the true merits of the case.

Bubonic plague then is present, and has been present for a considerable period, in the Chinese quarter of San Francisco, but, judging from the course of the disease in other civilized communities, it may be affirmed with a certain amount of confidence that there is little fear of the disease spreading. So long as it lasts its existence will be confined to the Chinese portion of the city, and it will menace but to a slight extent the remaining inhabitants of San Francisco.

At the same time it is satisfactory to the country at large, as well as to those more immediately concerned, that experts have made their pronouncement, and furthermore every one may now rest assured that by their advice the best methods known to extirpate and prevent the spread of plague will be rigidly enforced.

THE PROTOZOON OF CANCER.

HARVEY R. GAYLORD publishes in the *American Journal of the Medical Sciences*, May, 1901, a report of his cancer study during the past three years in the New York State Pathological Laboratory. He describes some incubation and inoculation experiments previously referred to in a communication made to the Medical Society of the State of New York in 1899. In a case of adeno-carcinoma of the peritoneum the greater portion of the tumor had undergone mucoid degeneration and the peritoneal cavity was filled with a clear, straw-colored fluid. This fluid, removed with every aseptic precaution, was found to contain a large number of small hyaline bodies, which were observed under the microscope to increase in size and change their form and pass through a cycle of development to what appeared to be a spore-forming stage. This fluid was injected into three animals—two, a dog and a guinea-pig, in the peritoneal cavity; one, a guinea-pig, in the jugular vein. The guinea-pig and dog which were inoculated in the peritoneal cavity developed no tumor, but a marked peritonitis and enlargement of the regional lymph nodes. The abdominal cavity of each animal contained a small amount of fluid; and in this fluid could be detected the characteristic spherical bodies, nucleated bodies, and sacs filled with granules present in the primary case. In slides taken from this fluid and incubated for a period of three or four days in the thermostat it was possible to trace the development of larger structures from the small hyaline forms.

Of particular interest was a portion of a slide so treated in which were found numbers of the organisms which had sent out pseudopodia toward a neighboring air-bell. In the animal injected in the jugular vein, killed after fifty days, the lungs were found to contain minute white nodules, which were beginning foci of adeno-carcinoma. The pulmonary blood-vessels showed marked proliferation of the epithelial and adventitial cells. The spleen of the animal contained a large amount of blood-pigment, and the Malpighian corpuscles were enlarged. The cells of the tumor and those of the enlarged follicles in the spleen were each found to contain within the nucleus irregularly shaped, deeply stained bodies of unusual appearance. About the periphery of the follicles and scattered through the splenic pulp were a number of round and oval bodies, which corresponded morphologically to what are known as Russell's fuchsin bodies. In the perivascular lymph spaces of the lung there has since been detected, by means of Plimmer's staining-method, the presence of the half-grown organisms in large numbers, which correspond to those described by him as of constant occurrence in carcinoma in man.

Early attempts to cultivate these organisms were negative in their results, but in later experiments Gaylord has succeeded in cultivating the organisms, directly from cancer, from fluids which were in contact with cancer, and from experimental animals. The culture medium which he has found to be most satisfactory is fucus crispus bouillon, recommended by Celli for the cultivation of amœbæ. The micro-organisms found in the peritoneal fluid were pale, spherical bodies from 2 μ to 10 μ in size. They were homogeneous, of pale, yellowish-green color, and at first were mistaken for fat droplets, although on closer examination their refractive index was seen to be too low. They were likewise resistant to ether, and when treated with osmic acid they failed to give the black reaction which characterizes fat. Attempts to stain them were partly successful. A few of the bodies contained granular material, which showed marked Brownian movement. The tubes were examined from day to day, and it was seen that the bodies slowly increased in size, became more indefinite, and gradually lost their yellowish-green color. As they increased in size they apparently became more fluid and commonly sent out pseudopods and long projections. Fine colorless granules appeared in the protoplasm, and in some a delicate nucleus could be made out. Ultimately the larger forms of the organism became transformed into what appeared to be large sacs containing highly refractive granules and small spherical bodies, not unlike the free spherical bodies above described. The membrane of the sac was demonstrable as a pale, colorless structure. The diameter of these sacs was on the average about 20 to 25 μ, or that of a good-sized epithelial cell. The author determined to his satisfaction that the yeast organism was not the essential cause of carcinoma and sarcoma and could not be confused with the organism already observed by him in fresh scrapings of carcinoma and in his experimental animals, and convinced himself of the identity of the organisms found in the fresh state and the forms known as Russell's bodies, Plimmer's bodies, and protozoon forms in the tissues. The organism is a protozoon belonging in the same group with the vaccine organism described by Funk in the *British Medical Journal* for February 23, 1901. It was found abundantly in all the organs, including the blood, in all cases of cancer examined, and in all cases in which cachexia was well marked the organism, especially in its younger forms, could be found in the peripheral blood.

News of the Week.

The Rivington Street Public Bath, which has been building for three years, is at last completed and open for the cleansing of the inhabitants of that densely crowded tenement district.

"Zeitschrift für Krankenpflege und Aerztliche Polytechnik."—Dr. Mendelsohn, of Berlin, has retired from the editorshhip of this journal, his place being taken by Drs. H. Reineboth, of Halle, and Richard Rosen, of Berlin.

Yellow Fever in Yucatan.—It is reported from Oaxaca, Mex., that a yellow-fever epidemic in Merida and other cities of Yucatan is causing many deaths, particularly among the foreigners. News has just been received of the death, of yellow fever, of Dr. Hormah Rubitsa, a prominent German physician of Merida.

The Missouri State Medical Association.—The annual meeting of this society will be held at Jefferson City on May 21–23, 1901, under the presidency of Dr. U. S. Wright, of Fayette. The programme contains titles of forty-four papers. The committee of arrangements consists of Drs. R. E. Young, J. L. Thorp, and J. N. Enloe.

College Rivalry in Hospital Appointments.—At the annual examination for internes at the Cincinnati City Hospital there were twenty-seven candidates, seventeen from the Ohio Medical College and ten from the Miami. Of these ten were successful in securing appointments, six from the Ohio and four from the Miami. There is always a rivalry between the two colleges at this examination, but the result was mostly a tie at this, though the Miami men claimed a slight advantage.

The Invention of the Ophthalmoscope.—Drs. Harry Friedenwald, of Baltimore, and Casey A. Wood, of Chicago, constitute a committee of the American Medical Association appointed to arrange the details for a commemoration at the St. Paul meeting of the fiftieth anniversary of the invention of the ophthalmoscope. In order to make the historical exhibit of ophthalmoscopes as complete as possible, the committee requests the loan of instruments of the older models from any who may have such in their possession.

Annual Report of Mount Sinai Hospital.—This report has been issued recently and shows that the hospital did excellent work during the year 1900, not-

withstanding its lack of space. In the period covered by the report 3,352 patients were cared for in the hospital, the total number of applications for admittance being 6,522, so that a large number of deserving cases were refused on account of the constantly crowded conditions of the wards. The officers of the Mount Sinai Hospital have long felt that, in order to relieve their sick adequately, new hospital buildings must be erected. This important work is now about to be commenced. The sum already subscribed toward this object is considerably over $1,000,000, and the directors are amply justified in expressing the opinion that the entire amount needed ($1,650,000) will be readily forthcoming, and will supply a splendid monument to the generosity of the Jewish community. It is confidently expected that the new hospital will be ready for occupancy in 1902.

A Gift to Muhlenberg Hospital.—Mr. J. Howard Wright, of this city, has placed $10,000 at the disposal of the board of governors of Muhlenberg Hospital, of Plainfield, N. J., for building an operating-room in connection with the proposed new hospital. The gift is a memorial to his grandsons, Howard Wright Corlies and Parker Wright Mason, who died at Plainfield last year.

University of Pennsylvania.—Mrs. C. B. Newbold has donated $25,000 for the construction of an obstetric amphitheatre in memory of her mother, Mrs. Thomas A. Scott. The new building will adjoin the west wing of the present maternity pavilion; it will be fifty feet square and will accommodate one hundred and fifty students. It will be provided with a complete sterilizing plant for instruments and dressings, and with a system for flooding the operating department after each operation.

American Congress of Tuberculosis.—The second annual meeting of the American Congress of Tuberculosis will be held at the Grand Central Palace, in the city of New York, on May 15 and 16, and perhaps 17, 1901, in joint session with the Medico-Legal Society of New York. The medical profession of all countries has been invited to contribute papers to be read before this Congress. As the questions to be discussed involve medical legislation, legislators, lawyers, judges, and all publicists who take an interest in the subject, are also invited both to enroll and contribute papers.

Army Dentists.—In the army bill passed recently by Congress, provision is made for the appointment of thirty dentists in the army. These are to be employed under contract, in the same way as are the acting assistant surgeons, their pay being $150 per month, and their term of service three years. They must be between twenty-four and forty years of age, and are to be engaged after an examination before a board of three dental surgeons appointed by the Secretary of War. The dental surgeon will be attached to the medical department, and will wear the uniform of an assistant surgeon with the rank of first lieutenant. Instruments and supplies will be furnished by the medical department; the dental surgeons will attend only to officers and men of the army, including acting assistant surgeons. The families of officers and civilian employees are not entitled to their services. Before nine o'clock in the morning and after four o'clock in the afternoon, however, dental surgeons may operate on others, and will be permitted to charge for such extra work.

Sir William MacCormac has been made a Knight Commander of the Order of the Bath, in recognition of his services in South Africa.

Removal of the Stomach.—The papers announce that Dr. B. B. Eads, of Chicago, has successfully exsected the entire stomach from a man named Paul Krüger, who is, however, not Oom Paul.

Dr. Nathaniel D. McDowell, of Rochester, has been appointed from the State civil-service list as optical surgeon at the State Industrial School. The salary is $40 a month.

A Monument to Professor Skene.—A movement is under way in Brooklyn to raise a fund of $25,000 for the erection of a bronze statue of the late Dr. A. J. C. Skene, of that borough, in Prospect Park.

Suicide in a Dispensary.—A patient shot himself in the head one afternoon last week while sitting on a bench awaiting his turn in the Bellevue Hospital College dispensary. He was under treatment for heart disease.

Dr. George Blumer, of the Bender Laboratory, Albany, has been appointed by the New York State health commissioner director of the newly established bureau of bacteriology and pathology of the State health department.

Insanity as a Ground for Divorce.—The Florida legislature has passed a bill providing that four successive years of insanity on the part of husband or wife is just ground for divorce. The person getting the divorce must provide means for the maintenance of the divorced one.

The Austro-Hungarian Hospital of New York.—A fund of $10,000 has been raised for the purpose of converting the East Side Dispensary, at 322 and 324 East Third Street, into the Austro-Hungarian Hospital. The work of reconstruction will begin on May 1st, and the new hospital with thirty free beds is to be ready about the middle of June. The name Austro-Hungarian was selected because many persons of that nationality have subscribed liberally toward defraying the cost of converting the dispensary into a hospital. The object of the hospital is mainly the care of the sick poor in that section of the city.

The British Casualties in South Africa.—Since the beginning of the Boer war 690 British officers and 13,734 men have been killed or have died of wounds or disease in South Africa; the missing and prisoners now amount to 17 officers and 758 men; 1,892 officers and 43,534 men have been sent home as invalids, of whom 4 officers and 300 men have died and 2,189 men have been discharged from the service as unfit, making

a grand total of 60,625; but of this total all but 711 officers and 16,692 men have returned to the field. In March of this year 4 officers and 103 men were killed, 26 officers and 270 men were wounded, 5 officers and 48 men died of wounds, and 3 officers and 36 men were missing or taken prisoners. Twelve officers and 406 men died of disease, and 129 officers and 2,940 men were sent home invalided.

A Monument to Bunsen, Kirchhoff, and Helmholtz.—A committee, largely composed of medical men, has been formed for the purpose of erecting a triple monument in Heidelberg to Bunsen, Kirchhoff, and Helmholtz. Special appeals for contributions are to be issued to learned societies and academies in the German empire, as well as to personal friends and admirers of the late scientists, but it is understood that the public at large will not be invited to contribute. The chairman of the committee is Dr. A. Kussmaul, of the University of Strasburg.

The Highest Death Rate in the World.—A cable despatch to *The Sun* from Durban, Natal, states that it is reported there that the Delagoa Bay district of Portuguese East Africa has been terribly affected by fever. In the last three months there have been five hundred deaths. The normal population is about three thousand, but this has been reduced owing to the war and the commercial depression resulting therefrom. This is the highest death rate in the world, and if it continues it will mean the extermination of the Europeans in that territory.

A Question of Privilege.—In a divorce suit recently tried in St. Louis the counsel for the plaintiff, the woman, wished to introduce the testimony of Dr. E. S. McKee, of Cincinnati, concerning a communication made to him by the husband regarding his wife, who was Dr. McKee's patient at the time. Dr. McKee refused repeatedly to testify before a notary in Cincinnati, holding that the communication was a privileged one, and was finally constructively committed to jail. The case was brought before Judge Hollister, of Cincinnati, who ruled that, as it was the woman and not the man who was the actual patient, the husband's communication was not a privileged one.

The Plague seems slowly but surely becoming pandemic throughout the world. Telegrams from Melbourne announce that the disease is increasing in the Australian commonwealth, and that there is much alarm over its spread. Another report states that eighteen thousand persons have died of the plague in the Lamko district of Hai-Nan island during the last few months. In letters from India to the State department at Washington, covering the period from November 4th to February 16th, it is reported that in Bombay alone there were 4,554 cases of plague, with 2,574 deaths, and in Calcutta 1,052 cases, of which 1,002 cases were fatal. At Cape Town, during the week ending April 20th, there were 64 new cases, 33 deaths, and 29 convalescents. Altogether there have been 455 cases of the disease, of which 113 patients have been Europeans. The total number of deaths has been 185, including 32 Europeans. The report of the commission appointed to investigate the plague in San Francisco, published by the surgeon-general of the marine-hospital service, has established beyond doubt, and greatly to the rage of the governor of California, that the disease prevails among the Chinese in that city.

Medical Association of Georgia.—At the recent meeting of this society the following officers were elected: *President*, Dr. James B. Baird, Atlanta, Ga.; *First Vice-President*, Dr. William H. Doughty, Jr., Augusta, Ga.; *Second Vice-President*, Dr. J. D. Chason, Bainbridge, Ga.; *Secretary and Treasurer*, Dr. Louis H. Jones, Atlanta, Ga. The association will hold its next meeting in Savannah on the third Wednesday in April, 1902.

Pathological Society of Philadelphia.—At the annual conversational meeting held April 25th, Dr. Charles Wardell Stiles, of the Bureau of Animal Industry, read a paper entitled "Trichinella Spiralis, Trichinosis, and Trichina Inspection—a Zoological Study in Public Medicine." He pointed out the importance of the discovery by Leidy of the parasite in pork more than fifty years ago, and the practicability of preventing infection by means of thorough curing and cooking. Man acquires trichinosis from swine, these from rats, and the latter from swine and other rats. The ova are matured in the intestinal tract, where the mature parasite extrudes enormous numbers of eggs, which gain entrance to the circulation and migrate to the muscles. Here they cause irritation with the generation of inflammatory products and the encystment of the parasite, which may survive for a long time, finally, however, to undergo calcification. For political reasons Germany has endeavored to exclude American pork on the pretext of the danger from trichinosis, and as a matter of fact actually did practise such exclusion for a period of nine years; but the evidence goes to show that trichinosis is less common in the United States than in Germany, and that little of the trichinosis in Germany can be traced to American pork, although Germany maintains a most expensive, though obviously not efficient, system of meat inspection. In the United States, on the other hand, only meat for export and for interstate consumption is inspected by the government, the greater importance being attached to perfect curing and thorough cooking. Fortunately, further, the vicious practice of eating uncooked pork is far less common in the United States than in Germany. Flesh for consumption within the borders of the State is subject only to local supervision; and inasmuch as two per cent. of swine are infected, it is obvious that too rigid precautions cannot be observed in the use and the preparation, especially of fresh pork.

Historical Club of the Department of Medicine of the University of Pennsylvania.—The first stated meeting of this club was held at the office of Dr. Charles A. Oliver on Wednesday evening, April 17, 1901, Dr. Oliver presiding. The club, which was organized in March, 1901, has for its object "the study of the history, with the collection, presentation, and

publication of data relating to the Department of Medicine of the University of Pennsylvania. Besides original research into the past history of the department, with the periodical publication of a series of proceedings, and the getting of a special library, it is intended that the club shall collect historical portraits, pictures, engravings, furniture, instruments, books, certificates, etc., to be placed in appropriate university quarters.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending April 27th. Assistant Surgeon J. B. Dennis detached from the Naval Academy and ordered to the *Chesapeake*, May 2d. Assistant Surgeon C. G. Smith ordered to the *Vermont*, April 25th. Medical Inspector F. Rogers ordered to the *Brooklyn* for duty as fleet surgeon of the Asiatic station. Surgeon W. F. Arnold detached from duty at Olongapo, P. I., and ordered to the *New Orleans*. Surgeon C. F. Stokes ordered to the Cavite naval station to await the *Solace*.

The Fifth International Congress of Physiologists will be held in Turin on September 17–23, 1901, under the presidency of Prof. Angelo Mosso. Americans wishing to participate in the work of the congress are requested to notify the secretary, Dr. Z. Treves, Corso Raffaelo, 30, Turin, and also Prof. Frederic S. Lee, Columbia University, New York. The congress fee is ten francs, to be paid to Dr. Treves in September. The official languages of the congress will be English, French, and German. No official report of the work of the congress will be published, and representatives of the medical or lay press will not be officially admitted to the congress, but each member is at liberty to offer his paper for publication to any journal he may select.

Obituary Notes.—Dr. James S. Carradine, of New York City, died at East Orange, N. J., on April 23d, of pneumonia. Dr. Carradine was born in Mississippi in 1839, was graduated from the University of Pennsylvania Medical College in 1858, and began the practice of his profession in New Orleans. At the outbreak of the Civil War he was appointed a surgeon in the Confederate army, serving through the war. Since that time he has practised in New York City. He was a member of the New York County Medical Association and the County Medical Society. A widow survives him.

Dr. J. Frank Williams, one of the most promising of the young physicians of Cincinnati, died in that city on April 8th, of diabetic coma. He was twenty-five years old.

Dr. Edward Watts Morris, of Birmingham, Ala., died in that city of pneumonia on April 23d, at the age of thirty-six years. He was born in Virginia, and was graduated from the Medical College of Virginia, Richmond, in 1885. He practised first in Richmond, but removed to Birmingham sixteen years ago.

Dr. Roy Inglis, of Jersey City, died on April 24th, at Denver, Col., where he went last fall for his health. He was born in Paterson in 1867, and was graduated from the College of Physicians and Surgeons of this city in 1890. He was for a time a member of the staff of the City Hospital of Jersey City and the German Hospital of this city. He began to practise in Jersey City in 1892. His widow, a daughter of the late Dr. B. A. Watson, and three children survive him.

Dr. Richard C. Baker, of Brooklyn, died at Otego, Otsego County, N. Y., on April 24th, of pulmonary tuberculosis. He was born in Otego forty-seven years ago, and was graduated from the New York University Medical College in 1874. He was secretary of the Brooklyn health department for several years, and was attending physician to the Eastern District Hospital.

Dr. Henry Byron McKellops, a well-known dental surgeon of St. Louis, died April 23d, at the age of seventy-eight years. He was born in New York State, and received the degree of D.D.S. from the Ohio Dental College in 1855. In 1865 he organized the Missouri Dental Association, and throughout his professional life was an active member of many local and national dental societies.

Dr. Samuel Griswold Dorr, of Buffalo, died suddenly on April 28th, of angina pectoris. He was born in Dansville, N. Y., in 1840, and was graduated from the Medical Department of the University of Buffalo in 1875. Since 1899 he had been postmaster of the city.

Dr. Charles K. D. Tanner, the "whip" of the Irish Nationalists in the British Parliament, died on April 22d, of pulmonary tuberculosis, at the age of fifty-one years. He was the son of a medical man and was himself a surgeon, having been lecturer on anatomy at Queen's College, Cork, and surgeon to the South Cork Infirmary and the County Hospital. He had sat for Cork in Parliament for fifteen years.

Obituary.

WILLIAM HENRY DRAPER, M.D.,

NEW YORK.

Dr. William H. Draper died of pneumonia at his home in this city on Friday morning, April 26th. He had been in failing health for more than a year, and last winter suffered an attack of influenza which left him more prostrated than before. About two weeks ago he was seized with pneumonia, to which he succumbed after a week's illness. He was buried from Grace Church on Monday morning.

Dr. Draper was born on October 14, 1830, in Brattleboro, Vt. He studied at Columbia College and was graduated in arts in 1851. He played the organ in St. Thomas' Church, while attending college, and in that way helped to earn his expenses. He studied medicine in the office of Dr. Willard Parker, and was graduated from the College of Physicians and Surgeons in 1855. He obtained his degree of Master of Arts from Columbia the same year. He then went abroad and studied in Paris and London for about a year, when he returned to this country and began the practice of medicine in this city. During the Civil War he made a trip of inspection to the Peninsula in connection with the sanitary commission. In 1869 he was appointed clinical professor of diseases of the skin at the College of

Physicians and Surgeons. He retired from that professorship after a time and took that of clinical medicine in the same college in 1879. He held that post until 1898. He then retired, but was appointed emeritus professor, which honor he held at the time of his death. He was a trustee of the College of Physicians and Surgeons until it became part of Columbia University, and then he was made a trustee of the university. He was appointed attending physician in the New York Hospital in 1862 and acted until 1889. Illness caused his retirement, but he remained consulting physician. In 1893 he became attending physician again, his health having permitted a resumption of this more arduous work. Altogether he served this hospital for thirty-nine years. Besides the New York Hospital Dr. Draper was connected with St. Luke's, the Presbyterian, Trinity, Roosevelt, the New York House of Mercy, and the Northwestern Dispensary. He was appointed attending physician at the Roosevelt Hospital upon its organization in 1871 and resigned in 1897, whereupon he became consulting physician there. He was president of the medical board of Roosevelt in 1893. He was at one time president of the Alumni Association of the College of Physicians and Surgeons. In 1886 he was president of the College of Physicians and Surgeons, and president of the Academy of Medicine. He belonged to the Association of American Physicians, of which he was a founder and one of the early presidents, the Academy of Medicine, the County Medical Society, the Pathological Society, and the Physicians' Mutual Aid Association.

Dr. Draper was the highest type of the general practitioner, of a cheerful disposition, a genial manner, and a scientific mind, full of medical knowledge, and eminently practical in his application of it at the bedside. He was a successful teacher, but was especially happy in his manner of discussing medical problems at society meetings. He was logical in his reasoning, clear in his language, and convincing in his arguments. As a consultant he was much sought after, and his counsel was always welcome and most helpful to patient and practitioner.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 25, 1901.

Chorea during Pregnancy.—F. S. Newell thinks that chorea deserves a special place in the pathology of pregnancy. It is not an accidental complication due to the recurrence of a previous infantile chorea, but in the majority of cases appears for the first time during pregnancy, and is to a great extent produced by this condition, although pregnancy alone cannot be regarded as the direct cause. Various conditions, such as heredity, previous infective diseases, etc., act as predisposing causes, and some nervous shock is usually the starting-point of the trouble. The prognosis is more grave than in early life. The principal drugs used in treatment are sedatives and alteratives. In grave cases ether and chloroform may be given as in eclampsia. Pinard gives chloral to prodnce almost continnous sleep, waking the patient only to administer food. When improvement in the choreic movements appears, the doses are diminished, but are continued until the movements entirely disappear.

A Special Form of Phlegmon of the Neck.—F. P. Emerson reports a case in which the neck was uniformly swollen down to the clavicle, presenting a three-lobed tumor separated by membranous septa, full and resistant throughout. There were no enlarged cervical glands; no redness; the neck was sensitive to pressure, and of a woody feel. There was great difficulty in swallowing and breathing. Ice poultices, alternating with unguentum resorcin, one drachm to the ounce of lanolin, were recommended; also cracked ice and a steam spray of campho-menthol, with supportive treatment, were given. Pus was seen exuding from the left side of the larynx; the discharge was gradual and convalescence uneventful. This would seem to be a case illustrative of the suppurative process described by Brousses and Brault, contained in what the authors call the glossothyro-epiglottidian cavity.

Experience in Search of a Cure for Asthma in the Far Southwest; with Observations of the Comparative Value of Different Sections in Respiratory Diseases.—Robert Bell from personal experience finds that asthma is much benefited in Arizona and a large perceutage of cures is made. He prefers Tucson to all other places for patients with chronic respiratory disease. It stands on a mesa of twenty-four hundred feet elevation, has an annual rainfall of eight to ten inches, and is singularly free from wind, dust, and sudden changes of temperature because it is nearly surrounded by high mountains. It has a maximum of sunshine and is a desirable place to live in, meeting all the requirements of civilized life. The author gives much excellent advice in regard to practical points to be observed in sending patients to the far Southwest.

Remarks on Anæsthesia, General, Local, and Spinal.—By Maurice H. Richardson.

Notes on X-Light.—By William Rollins.

New York Medical Journal, April 27, 1901.

The Relation of Arterial Changes to the Heart.—Beverley Robinson says that in cases in which arterial sclerosis comes on early we should take account of heredity as a possible factor. Other factors are imperfect assimilation of food, irregular hours, working too soon after eating, etc., all acting by changing both quantity and quality of the blood. Renal disease may be only a secondary manifestation of arteriosclerosis. In the nodular form of the latter anenrismal dilatation is no uncommon seqnence. The diffuse form of arteriosclerosis is frequently found among middle-aged men and particularly those who are strong and vigorous. It is in this form that we usually find cardiac hypertrophy, but as a rule unless the coronary arteries are involved there is no fibrous myocarditis. Cases of cardiac insufficiency following hypertrophy due to arterial changes are frequently mistaken for chronic valvular diseases, especially when there is a blowing systolic apex murmur. Such cases call for strychnine, digitalis, and strophanthus, while it is also advisable to give the iodide in moderate doses and for long periods with occasional interruptions. Local or general blood-letting may be of service in threatened heart failure in hypertrophic dilatation. A few leeches to the præcordium will often give great satisfaction when all drugs have failed.

A Combined Intranasal and Extranasal Operation for the Correction of a Congenital Concave Vertical and Lateral Deformity of the Nose; with the Report of a Case.—By B. S. Booth. The steps of the operation must be read in the original article. The author incidentally discusses the relative advantages in these cases of general anæsthesia and the combined use of cocaine and suprarenal extract. He prefers the latter course for the following reasons: (1) There is less immediate danger from heart failure or suspension of breathing. (2) The hemorrhage during the operation is *nil*. (3) The operator can see what he is doing at every step during the operation. (4) The patient can sit upright and hold his head in place during the operation—an obvious advantage. (5) No special instruments are necessary—a step toward simplifying the operation. (6) The operation can be done as well in an office as in a hospital. This not only saves time and expense, but will be preferable to a large percentage of patients. (7) The pain is insignificant, and certainly less distressing than are the nausea and vomiting following the use of ether.

Hospital Appointments: Are They Open to Women?—Miss Helen MacMurchy, M.B., has collected figures bearing on this question, compiling her information especially for the Woman's Medical College in Toronto. From a lengthy list of appointments it appears that there are in all 559 medical appointments—government, municipal, and hospital—held by women physicians (and also 11 appointments recently opened to competition). Of these, 215 are resident; 302 (including 114 resident) are in the United States, and 188 (including 99 resident) are in the British empire.

A Contribution to the Explanation of the Nature of the So-Called Predisposition to Infection with Staphylococci.—From a series of experiments with the staphylococcus pyogenes aureus on rabbits, F. W. Gaertner concludes that in states of anæmia consequent on bleeding and starving, infected animals showed a quicker multiplication of the germs than did normal animals infected under similar conditions. He therefore does not hesitate to conclude that the conditions which favor a disposition to infectious diseases have to be looked for in the hydræmia of anæmia.

Peripheral "Anæsthesia Paralysis"; Report of an Unusual Case of Bilateral Brachial Paralysis Occurring during Narcosis (for Appendicitis).—By W. M. Buckner.

Pneumonia; its Proper Management in Children.—By Louis Fischer.

Tenonitis and Tenotothecitis Proïifera Calcarea.—By Carl Beck.

Philadelphia Medical Journal, April 27, 1901.

Scurvy in Infants.—Louis Starr tersely states that the cause of scurvy in infants is continued deprivation of fresh food. The faulty foods he classes as follows: The different proprietary infants' foods administered without or with slight addition of cow's milk; these foods are responsible for the greatest number of cases, and the variety most harmful depends greatly upon the degree to which it is used; oatmeal or wheat gruel; barley and other farinaceæ administered with water alone or with water and insufficient cow's milk; condensed milk and water; sterilized milk; properly modified milk mixtures, but subjected to a temperature of 212° F. from thirty minutes to an hour or more; too dilute milk-and-cream mixtures; laboratory mixtures with too low albuminoid percentages. Scurvy is found more frequently in infants reared in luxury than in the very poor. The essential cause of this disease is unknown, but it is acknowledged that it is due to some peculiar deprivation. Very few post-mortem examinations are on record, as very few cases are fatal. The anatomical lesions are chiefly due to hemorrhage, the most characteristic being the subperiosteal blood effusions about the shafts of the femora and tibiæ, sometimes of the long bones of the arms or of the cranium and thorax. Hyperæsthesia is almost invariably the initial symptom. Immobility follows. The general features are very diverse in degree of prominence. The essential treatment is the employment of a food composed of cow's milk, cream, water, and milk-sugar, the milk and cream not having been passed through the separator and not sterilized. The juice of fresh ripe fruit—orange juice especially—is a useful addition to the diet. An appropriate food schedule for scurvy in an infant of eight months is: At 7 A.M., cream, ½ ounce; milk, 4½ ounces; milk sugar, 1 drachm; water, 3 ounces. At 9 A.M., one to two teaspoonfuls of fresh orange juice, according to effect on the bowels. At 10:30 A.M., same as at 7 A.M. At 11:30 A.M., two teaspoonfuls of raw beef juice, free from fat, and with a little salt. At 1 P.M., one to two teaspoonfuls of fresh orange juice. At 2 P.M., same as at 7 A.M. At 3 P.M., two teaspoonfuls of raw-beef juice with salt. At 5 P.M., one to two teaspoonfuls of fresh orange juice. At 6 P.M., same as at 7 A.M. At 8 P.M., two teaspoonfuls of raw-beef juice with salt. At 10 P.M., same as at 7 A.M. A substitute for orange juice may consist in scraped ripe apple or fresh grape juice. Iron is indicated. The body may be gently rubbed with warm olive oil. Complications must be met as they arise.

Journal of the American Medical Ass'n, April 21, 1901.

When Should Patients be Advised to Eat Everything?—Boardman Reed says we should never advise our patients to "eat everything" until we have thoroughly cured their diseased digestive organs and freed them from the lithæmic condition; and, powerful as are our modern weapons against these, we cannot often succeed in accomplishing such a radical cure until the patients have reformed their unhygienic habits, not only in their eating and drinking, but also in both their work and play. They must learn self-denial and at least the rudiments of the immutable laws of health, and, having learned, obey them. They must take into their stomachs, in approximately right proportions, the things that will nourish and strengthen them, and little or none of those whose chief effect is to derange or irritate the functions or tissues of the body. In many cases, besides, they must give up sedentary employments or pleasures and take regularly, every day, an adequate amount of exercise out-of-doors. In short, oxygenation must be made to bear its proper ratio to alimentation. Nor should we advise even the well persons in the families under our charge to "eat everything," without some regard to their idiosyncrasies and tendencies, as well as a reasonable amount of care that they do not follow a harmful acquired taste for too much of the rich and complicated viands or such an undue proportion of nitrogenous food as would make patients of them a few years later, by setting up gradually insidious forms of chronic disease which would inevitably result, at a relatively early period of their lives, in gout or rheumatism, or in other more serious and fatal organic affections.

Poisoning from Auto-Intoxication.—T. D. Crothers confines his remarks to the effects of alcohol, which he claims leads to a poisonous action on the system, laying down the following propositions: (1) Alcohol in any form, taken into the body as a beverage, is not only a poison but produces other poisons, and associated with other substances may develop toxins. Alcohol is also an anæsthetic and not a tonic or so-called stimulant. It increases the waste products of the body and diminishes the power of elimination. It also destroys the phagocytes of the blood, and thus removes and lessens the protective power of the blood cells. (2) Whenever alcohol is used continuously as a beverage, for its medicinal effects, favorable conditions and soils for the cultivation and growth of poisoned compounds are created. These may be neutralized by other conditions and not be apparent in the derangements of the functional activities which follow. (3) The functional and organic symptoms of derangement appearing in those who use spirits in moderation or excess, which quickly disappear by abstinence and eliminative measures, are clear indications of auto-intoxications from this source. (4) The treatment of all such cases, in which alcohol is used in any form, should be by antiseptic and eliminative measures, and the supposition should always include the possibility of poison by chemical products formed in the body.

A Rule for Combining Crossed Cylinders.—H. S. Pearse gives the following formula to transpose crossed cylinders into a sphero-cylinder: "The cylinder is the sum of the two cylinders with the sign and axis of one of the cylinders. The sphere is the strength of the other cylinder with its sign." Example:

$$-1 \text{ c. axis } 180^\circ \supset +2 \text{ c. axis } 90^\circ =$$
$$-1 \text{ s.} \supset +3 \text{ c. axis } 90^\circ, \text{ or}$$
$$+2 \text{ s.} \supset -3 \text{ c. axis } 180^\circ.$$

The use of the lighter and thinner lens is always to be aimed at and will usually give the best result; occasionally, however, the heavier lens will be more satisfactory, and rarely there are cases in which only the crossed cylinders will be accepted. It is in retinoscopy especially that the student will find rules of this character of great value, for there are always two meridians to be reduced to a sphere or a sphero-cylinder. The experienced refractionist will not need them.

Floating Kidneys in Children.—J. A. Abt reports five cases. The etiology in this condition is not clear. Floating kidney may be only one symptom of a general enteroptosis. Traumatism is doubtless a very frequent cause. In very young infants the condition must be regarded as congenital. In older children there can be doubt that a congenital tendency exists, while the exciting cause is an acute or chronic trauma. The latter expression has reference to causes which are constantly acting or at least are of frequent occurrence, eventually dislodging the kidney from its fixed position. The symptoms consist of pain, colicky or paroxysmal in character, and possibly accompanied by chill, fever, vomiting, and sweating. The urine may be diminished, while the kidney is usually sensitive. Symptoms referable to the gastro-intestinal organs are not uncommon.

The Medical Man in the Navy.—W. K. Van Reypen states that the medical corps of the navy is recruited directly from civil life. A permit to appear before a naval medical examining-board will be given to an applicant between twenty-one and thirty years of age who presents satisfactory references. Political and other influences are eliminated in these appointments, and merit only is considered. The order of examination is as follows: (1) Physical; (2) written; (3) oral; (4) clinical; (5) practical. In the written examination a thesis is written upon some professional subject. Besides this there are questions on hygiene, quarantine, etc. The oral examination includes the usual professional branches. In the clinical examination the microscope, thermometer, laryngoscope, ophthalmoscope, and other aids to physical diagnosis are made use of. In the practical part are surgical operations on the cadaver, the application of splints, bandages, surgical dressings, while chemical and pharmaceutical manipula-

tions are included. Naval life includes travel at home and abroad, with a period at sea and a period on shore in one's own country with service in different naval hospitals or shore stations. This life offers varied and wide opportunities to the medical man.

The Municipal Health Department System, and More Especially in Reference to its Advantages and Disadvantages as an Opening for the Young Medical Graduate.—Arthur R. Guerard proves that both the mortality from and prevalence of disease are being reduced by modern sanitary science and preventive medicine. The sanitary bureau of the board of health of New York City includes six divisions: (1) General and special sanitary inspection. (2) Contagious diseases and medical sanitary inspection. (3) Food inspection, offensive trades, etc. (4) Pathology and bacteriology. (5) Medical school inspection. (6) Marine inspection. There are four hospitals under the control of the board of health. Appointments to the health department are governed by civil-service rules. Competitive examination is always necessary. The salaries average about $1,200 a year. As a rule Sundays and holidays are free. There is a vacation of two weeks in the year. The medical health officer is liable to become unpopular. The obstacles in the way of appointment are great. However, this work opens up a broad field and offers rich opportunities for doing good.

The Outlook for the Young Physician in State Hospital and Sanitarium Work.—Carlos F. MacDonald declares that the medical service in state hospitals for the insane offers a most inviting field for clinical study to the young physician, and a comparatively generous compensation. Each State hospital is legally required to have one woman physician on the staff at an annual salary of $1,000 to $1,500 and maintenance, but who is not in the line of promotion. The State is most liberal in providing for the living of its officers. As to private institutions for the insane, they are of two kinds: incorporated private asylums, or hospitals, and small sanatoria that are conducted on the "family plan." The clinical advantages in the former are good, but the pay and allowances are generally less than in the State institutions. In the private sanatroia clinical opportunities are meagre.

The Medical Man in the United States Marine-Hospital Service.—The Treasury Department of the United States government offers to those capable of filling the positions an assured income and excellent social position. This is practically an appointment for life. The examinations are most rigid. A successful applicant is appointed to the grade of assistant surgeon with a salary of $1,600 per annum. There is opportunity for the varied talents of the different officers of the service to be exercised and thereby secure the promotion of their successor. Wire-pulling and political influence cannot give a man one of these life positions if he is not by his own merits commended to the examiners.

The Advantages in Examining for Life Insurance.—Brandreth Symonds believes that this work is most advantageous to physicians. The compensation is good for the work required. The fee for an examination is generally $5. This includes the filling in of question blanks, a thorough physical examination, and a chemical examination of the urine. An insurance examiner is considered among the first of his associates. The sphere of observation is enlarged in this work and an insight into human nature gained. The discipline gained in the pursuance of this work is invaluable. The work is exacting, and requires skill and alertness.

The Study of Internal Medicine.—By William Osler.

British Medical Journal, April 20, 1901.

Veld Sores.—Alexander Ogston believes that this disease is peculiar to South Africa. Veld sores resemble epidermic vesication but are not vesicles. These sores occur mostly on the hands and forearms, as well as on the feet and legs; not so often on the less exposed parts of the body. They are not frequent on the face. Suppuration is not a characteristic of this lesion. A break in the continuity of the skin seems to be necessary for the origin of the disease. It may often result from the bites of insects. Usually it is due to the inoculation of a virus into an existing abrasion by house flies. The serum appears to contain a pure culture of a peculiar micrococcus. This micrococcus campaneus is probably an inhabitant of the vegetation and soil of the veld. In treating the sores, after as much epidermis as possible has been removed, any good antiseptic, as carbolic or salicylic acid applied in solution or in vaseline, speedily brings about a cure.

Enteric Fever in South Africa: Effective Sterilization of Excreta.—H. A. Cummins from experiments shows that by the present methods of disposal of stools many bacteria survive half a minute, while after one minute only one species remained alive. At two minutes all forms of life had become extinct. Even spores lost their vitality. The cauldron into which all waste is emptied has a capacity of forty gallons. It is emptied every evening for cleansing purposes; twenty gallons of a solution of izal or crude carbolic acid in water, ʒ ss. to the gallon, is poured in, and when heated to near boiling-point the apparatus is again fit for use. No nuisance is caused. Smell is practically absent.

Venesection in the Treatment of Gunshot Wounds of the Chest.—F. J. W. Porter reports the case of a lieutenant who was shot through the right chest. There was a good deal of hemorrhage into the right pleural cavity. He was put into an ambulance, but suffered so from the jolting that he required morphine. His condition became so bad, the pulse small, the heart's impulse diffuse, the lividity great, that the writer withdrew about ten ounces of very dark blood from the median basilic vein. The patient made an uninterrupted recovery. His heart had been unable to drive the blood through the undamaged lung, and was relieved by the reduction of the volume of blood.

Some Observations on Veld Sore.—W. H. Harland states that this sore is first noticed as a small papule which rapidly increases in size. It is filled with clear, yellowish serum which soon becomes turbid. The skin overlying is thin and fragile. The sore is somewhat painful and dirty-looking, covered with a dirty scab, exuding serum and pus freely. The sores are generally multiple. The treatment is simple, consisting in incision with application of boric or carbolic fomentations. The most probable cause is the sting of the large brown horse-fly.

The Lancet, April 20, 1901.

On the Causation and Treatment of Profuse Epistaxis in People Beyond Middle Age.—George Coates gives abstracts of histories of several cases, in all of which the sequence of events leading up to the hemorrhage was the same, namely: (1) long-continued arterial pressure; (2) some sudden cardiac failure; (3) over-filling of the whole venous system, the weakened heart not being sufficiently able to empty the engorged veins against the high pressure in the arterial system due to contracted arterioles; (4) leakage from an over-filled vein. The most scientific and satisfactory treatment of these cases of epistaxis, and by analogy of the other forms of passive venous hemorrhage, is to empty the overfilled veins. As long as they are enormously distended with blood the hemorrhage must continue unless direct mechanical means are used, and if one nostril be plugged the epistaxis is apt to start from the other. If, on the contrary, we can relax the walls of the arteries and help the enfeebled heart to do its work, it will soon empty the overfilled veins. But, as a rule, this cannot be done by giving heart tonics at first. Immediate treatment must be directed to the capillaries and small arteries, as the real cause of the epistaxis lies there, not in the nose. Nitroglycerin is quite effective, nitrite of amyl might be more so, but one of the more quickly acting nitrites should be used at first; afterward one of the more slowly acting, as erythrol tetranitrate or possibly even thyroid tabloids, might do as well. When the capillaries and arterioles are dilated and pervious, then comes the time for strychnine or strophanthus. In spite of everything plugging may have to be resorted to in some cases, but in most of them the hemorrhage can be stopped without resort to this procedure, which is always most uncomfortable to the patient and sometimes even dangerous.

When to Operate in Perforative Peritonitis.—A. C. Roper calls attention to the fact that in cases of suspected perforative peritonitis we must first exclude the possibility of hepatic or renal colic. If the patient is rolling about in bed, he probably has colic of some kind, intestinal, biliary, or renal. Patients with peritonitis keep their abdominal muscles very still. Though they may toss the arms or the head about, they do not move the abdomen. Roper considers the four cardinal signs of perforation in

the early stage (*i.e.*, for the first few hours after it has occurred) to be rigidity, tenderness, presence of fluid and free gas in the peritoneum, to which may be added the pain and signs of collapse. Several hours later one may find: (1) Rigidity giving place to distention, but still there is immobility in respiration. (2) Tenderness still present, though in less degree and not so general. In an appendix case the localization of the pain at this stage may be an invaluable guide. (3) Free fluid probably increased, though it must not be forgotten that great distention of the intestines may obliterate the percussion dulness in the flanks by displacing the fluid. (4) One will probably find that neither fæces nor wind have passed per rectum. This period is the golden opportunity for operating, or even for removing a patient to a hospital or place suitable for operating in; and, while the writer personally would not deliberately wait for it as the elective period for operation, yet he would not, having made his diagnosis at an earlier stage, or seeing the case for the first time in this stage, when a competent man had earlier diagnosed perforation, refuse to operate because the patient had apparently become so much better.

The Open-Air Treatment of Phthisis at Home; a Short History of a Case.—By F. W. Bartlett. The case is that of a woman of thirty-eight years, who lived in the country. Removal to a sanatorium was out of the question, so she lived for one whole winter in the daytime in a shepherd's van, which was moved into the garden at the rear of her house. A small stove kept the van warm enough for comfort. At night she slept in her house, the windows (screened) being always open. She confined herself to a plain but nutritious country diet, and took creosote sparingly with a terebene cough mixture. The results were fully as good as those usually obtainable in an institution, and the case is reported to encourage the further adaptation of this sensible mode of treating pulmonary tuberculosis in the cases of those who for various reasons are compelled to remain at home.

A Case of Recovery after Operation for Diffuse Peritonitis from Perforation of the Appendix.—By C. A. Morton. The author does not believe that the infection in his case involved the upper part of the peritoneal cavity. It occurred in the course of a fourth attack of appendicitis in a man of forty-four years. Operation was done about forty-eight hours after the initial symptoms. The patient did well after operation. In ten days the abdomen was soft and of natural shape, and he was taking fish and other kinds of solid food. Noteworthy symptomatic features in the case were a pulse hardly above normal, very slight fever, no vomiting, and no signs of general prostration.

Movable Kidney and its Treatment (Surgical Treatment Excepted).—Roskam states that the movable kidney is almost always on the right, almost never on the left. It occurs especially in women. The time most favorable for its appearance is from the establishment of the menses to the end of the menopause. The young girls affected by this trouble are more numerous than married women. The symptom of pain varies with the position of the kidney. The pain is more severe in the slighter degrees of displacement. Digestive troubles are most characteristic, and vary from the simplest form of dyspepsia to serious disorders. The stomach gives the first signs—a feeling of heaviness with the evolution of gas. Vertigo, cardiac palpitations, and constipation occur. There may be true gastric crises with vomiting. Symptoms on the part of the liver are common. Nervous complications are not rare. Massage does not have a favorable effect on the movable kidney, and only a limited action on certain concomitant troubles in the cases of enteroptosis, but it has a real value in certain lesions of the large intestine. The physician should strive to immobilize the kidney in such a position that the patient will not suffer in attending to her affairs. Sudden movements should be avoided. The patient should as soon as menstruation occurs go to bed. The style of bandage appropriate to be worn will vary with the degree of displacement. When necessity for massage appears it can be resorted to. Static electricity is good for neurasthenics, but the treatment giving the best results in the author's opinion is a combination of electricity, massage, and hydrotherapy. In patients affected by neurasthenia or hysteria, all causes of irritation should be removed, even if this necessitates operation. Every painful movable kidney capable of producing reflexes provokes disturbances in the digestive system with the production of toxins. Operation should be proposed without hesitation.—*Annales de la Société Médico-Chirurgicale de Liège*, March, 1901.

A Case of Malignant Osseous Tumor.—Laffarelle reports this case of a man aged fifty-three years. He first complained of pain in the right hip in March, 1899. The pain continued, although it was ameliorated from time to time. The diagnosis of aneurism was made, since the tumor, which was increasing in size, pulsated. This was thought to have destroyed the vertebræ at its site and to be pressing upon the nerves which supplied the lower extremities. In November the right lung became affected by tuberculosis, in December the left, and at the same time a tumor appeared at the level of the second rib. On January 8, 1901, the patient died. The suffering had at times been excruciating. Only a partial autopsy was allowed. The tumor in the chest was examined. It was round and about the size of an orauge. It was surrouuded on all sides by muscle, from which it was separated by an envelope of connective tissue. On section, the tissue appeared soft, of uniform red coloration, from which escaped a large quantity of blood. The tumor had evidently originated from the periosteum, and consisted of young connective tissue and of chondromatous tissue at the periphery. The centre was soft. It evidently belonged to the type of tumor called alveolar sarcoma. Hildebrand first described it under the name of endothelioma of bone. The cachexia was late in developing, and the patient in spite of his pain kept in good condition, and it was tuberculosis which caused his sudden death. This case differed in its symptoms to a certain extent from the typical description, for the evolution was not remarkably rapid, the malignancy was not demonstrated, and the generalization was not rapid. The pulsations, however, were present, and the bone near the tumor was destroyed.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, April 14, 1901.

Pulmonary Complications of Influenza.—Ed. Michel states that among the infections la grippe has the most frequent and varied pulmonary complications. The toxins of this disease seem to affect particularly the nervous system. The reaction is felt in various parts of the body, but especially in the lungs. These pulmonary complications of grippe may be comprised in two classes: (1) Diverse congestive manifestations probably due to grippe alone; (2) pulmonary complications dependent upon the agents of a secondary infection. Among the first are simple catarrh, congestive bronchitis, congestion of the entire chest, diaphragmatic pleurisy, and hæmoptysis. Examples of the second class are broncho-pneumonia and pneumonia. The characteristics of grippal pneumonia and broncho-pneumonia are insidiousness of onset, slow resolution, and painful convalescence. Abscess of the lung may develop. The prognosis depends upon the nature of the pulmonary process. It is good for the simple congestive forms, but extremely bad for pneumonia and broncho-pneumonia. The best treatment for these severe cases seems to be serum injections, and local or general application of cold.—*Le Bulletin Médical*, March 30, 1901.

Note on the Leucocytic Reaction, Both Local and General, in a Severe Case of Jaundice.—Paul Caziot, from careful blood examinations of a severe case of jaundice, concludes that in grave jaundice with acute hypertrophy of the liver the hyperleucocytoses, both locally and in the circulating blood, are parallel from a quantitative point of view. In this case they were parallel also qualitatively at the sixth day, for, considering the high degree of leucocytosis of the blood, there could be said to be a relatively large number of mononuclears in the circulating blood. The parallelism disappeared at the time of death, as at that time the number of multinuclears was very marked. As in pneumonia, increase of leucocytes with considerable increase in the proportion of multinuclears indicates an extremely grave prognosis. The grave form of jaundice is a general infectious malady accompanied by hypertrophy of the lymphoid organs as a means of defence.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, April 11, 1901.

Study of the Causes of Death in Serious and Extensive Burns, and of the Injection of Large Amounts of Salt Water as a Therapeutic Means.—Adrien Besson concludes his article in this number with the study of injections of salt water. By diluting the blood with suitable liquids, dehydration of the tissues is guarded against by restoring to them the water which they have lost. Their important

functions are renewed and blood pressure is raised. The blood circulates normally and gives nutrition to the parts. Distribution of heat is equalized and nutritive changes are reanimated. Visceral circulation is modified and the blood is freed from the toxins elaborated when nutrition was at a low ebb and when the eliminative organs were not acting normally. The blood is actually washed.—*Journal des Sciences Médicales de Lille*, April 6, 1901.

Three Cases of Restoration of the Nose in Hypertrophic Acne.—J. Pantaloni believes the method of cure used in these cases, which he reports, to be the best. It consists in the complete ablation of the hypertrophied parts. This excision is sufficient in the majority of cases without recourse to immediate rhinoplasty. The excision may be made with scissors and bistoury, but with the former one can work more quickly and easily. It seems more truly surgical. Sometimes plastic operations on the nose are necessary later, but ordinarily immediate rhinoplasty is useless.—*Archives Provinciales de Chirurgie*, April 1, 1901.

Deutsche med. Wochenschrift, April 4, 1901.

Acute Yellow Atrophy of the Liver Terminating in Recovery.—Albu reports this case, which makes the eighteenth that has been published. The patient was a man of thirty-six years, with a negative past history, who three weeks before coming under observation had become jaundiced after an emotional shock. This condition continued for some time until mental hebetude and great prostration developed, when the author was called to the case. There were then noted profound muscular weakness without any emaciation, slight impairment of the mental faculties, a temperature of 103°, and slow pulse. The liver dulness was greatly decreased, extending from the sixth rib only two inches downward, there being tympany under the free costal arch. The spleen was palpable, the urine bile-stained and containing no albumin, but large amounts of indican, leucin, and tyrosin. The stools were acholic. At the end of the sixth week from the first access of the jaundice the temperature stayed down permanently, the liver dulness began to increase, and the enlarged spleen receded. The patient soon regained his former strength and vigor, though the jaundice did not wholly disappear until about three months later.

The Detection of Minute Traces of Albumin.—A. Pramm describes a method of facilitating the detection of albumin in the urine in amounts so small as to give only very slight cloudiness. A small quantity of the suspected urine is filtered into a test tube and a few drops of the reagent are added. Sulphosalicylic acid in concentrated solution is highly recommended for this purpose, though other substances may be used. The funnel is again put into the test tube and a little more urine filtered through, taking care that the stream flows down the side of the tube (which may be facilitated by the use of a funnel with the stem obliquely ground), so that it will form a layer on top of the first portion. The two now being in one tube, accurate comparison is possible, and minute precipitates that might otherwise pass unnoticed are easily detected.

The Treatment of Fresh Cases of Tropical Dysentery.—R. Ruge's experience with Plehn's method of calomel treatment for this disease has not been so satisfactory as the long-established ipecac therapy. Plehn recommends calomel in one-grain doses given every hour twelve times a day, and avers that salivation is produced but rarely. Ruge was less fortunate, and caused severe stomatitis without sensibly affecting the disease, while infusion of ipecac with milk diet invariably gave him satisfactory results. The infusion should not be stronger than 1 : 40, and may be given three times daily in doses not exceeding two and one-half ounces.

The Soluble Iron in Natural Ferruginous Waters.—By C. Binz.

Max von Pettenkofer.—By F. Erismann.

Berliner klinische Wochenschrift, April 1 and 8, 1901.

A Remarkable Form of Urticaria Factitia Accompanying Scleroderma.—Bettman describes two cases of scleroderma which presented at the same time an unusual type of dermatographia. Urticaria is of itself not a rare complication of scleroderma and appears to be simply a concomitant vasomotor phenomenon, which by some authors is regarded as an initial stage of the disease; but in the two cases described the symptom was remarkable for the length of time during which the wheals persisted after the skin had been irritated. Scratching the surface of the chest or back with the finger nail caused the appearance of the usual elevated markings, which in the one case regularly persisted as long as twenty hours and in the other five or six days. In addition to this wholly unprecedented duration of the phenomenon, the cases were also atypical in the slowness with which it appeared, a number of minutes usually elapsing before a perceptible elevation of the skin was produced.

The Prognosis of Brain Diseases in Children.—(Concluding article.) H. Oppenheim describes a series of cases in which the symptoms suggested the presence of brain tumors, but in which the use of combinations of iron and iodine led to full recovery. None of the children presented any evidences of inherited or acquired syphilis. Oppenheim is inclined to believe that the cases were due to a localized meningo-encephalitis of a tuberculous nature, affecting especially the motor zone of the brain, and that such a lesion is curable by the establishment of retrograde changes in the tuberculous deposits and subsequent cicatrization. The condition has been called by French writers "méningite en plaque tuberculeuse."

A Case of Idiopathic Hemorrhage between the Retina and the Vitreous.—H. Ziegner reports the case of a man aged fifty-two years, who suddenly noticed while at work a dimming of vision in the right eye. Upon consulting his physician it was found that there was a collection of blood between the vitreous body and the retina. The mode of treatment is of interest in that absorption of the clot seemed to be greatly hastened by the subconjunctival injection of solution of common salt, 1 c.c. being used for each injection. Under this treatment the clot was entirely absorbed and vision was restored.

A Case of Splenic Anæmia with many Mononuclear Neutrophile Leucocytes.—G. Freund presents a detailed enumeration of the various kinds and numbers of the different forms of blood cells found. The treatment consisted in the use of arsenic both internally and by hypodermic injection. The patient's subjective condition was greatly benefited, but the size of the spleen was not affected.

The Journal of Tropical Medicine, April 1, 1901.

A Case of Quartan, Showing Cyclic Variation of Parasites.—G. Douglas Gray reports the case of a native Indian suffering from typical quartan fever. Blood examinations were made during three entire cycles before quinine was given. During the first observed, but really fourth cycle, there was an average of 500 parasites; during the second observed cycle an average of 446 per cubic millimetre; during the third an average of 627; and the fourth observed cycle showed an average of 302 parasites per cubic millimetre. Quinine was then given and continued, though the parasites did not immediately disappear, and three days later 210 per cubic millimetre were still present; on the following day 35 per cubic millimetre were found, and later on only so occasionally that the number could not be estimated. If uninterrupted multiplication existed and the parasites in the first observed cycle were 500, in the second they should have been at least 3,000, in the third 18,000, and at the commencement of the fourth cycle 108,000. Some natural check to such multiplication must have existed. These observations have an important bearing both on natural cure and immunity, and on the protracted periods during which the parasites appear to be latent.

A Case of Yellow Fever at Saltpond, Gold Coast.—S. Osborne Browne reports the case of a Scotchman whose illness lasted four days, terminating fatally. Temperature started at 104° F., fell to 102° under medication, but rose again to 104° before death. Black vomit appeared on the third day. The patient had been only one year in the tropics. Although a teetotaller at home, he took stimulants on the coast, and for some time before his last illness had eaten oranges immoderately, and was often ill from dealing with rubber. His residence was in a good position on rising ground, clean, new, and not very near native houses or the lagoon. His illness occurred in the height of the dry season, and mosquitos were conspicuous by their absence, although a few existed, especially Culex.

Reviews and Notices.

The Theory and Practice of Military Hygiene. By Edward L. Munson, A.M., M.D., Captain Medical Department, U. S. A. 8vo, pp. 971. New York: William Wood & Company. 1901.

In his preface the author very truly states that, "save a small collection of sanitary precepts intended for the use of officers of the line, no book exclusively devoted to the preservation of the health of troops has been published in the English language for more than a generation."

When are taken into account the great and fundamental advances made during this period in military and other forms of hygiene and disease prevention, and the great necessity of formulating the valuable material accumulated, the great need for the present work is without question.

The best that can be said of the efforts of the author is that his work is destined to take its place as the leading and most comprehensive one on the subject in any language. In a word, it deserves the highest praise for its thoroughness, scope, and adaptability to the needs not only of the military surgeon but of the student of hygiene in general.

Every subject is treated with clearness; and the painstaking collection of accurate data, the tabulation of valuable statistics, and the logical treatment of their relative significance and value, prove the eminent fitness of the author for the work on hand.

The arrangement of the book is thoroughly systematic and affords ample opportunities for ready reference in the order of importance of the topics discussed.

The selection and development of the recruit and his care during the march comprise an amount of useful and practical information never before presented in such readable and intelligible form.

The chapters on Water and Ration are particularly valuable and are treated in a plain and comprehensive way. The diseases which come from a bad water supply are fully described, and the chemical and bacteriological methods of their propagation are quite exhaustively presented and are suitably illustrated. Particular attention is paid to the proper selection of wells, and the different means of filtration are virtually exhaustive in the application to different forced conditions of environment.

Ventilation also receives its due consideration in connection with the practical application of advanced theories to primitive conditions.

The nutritive qualities of different foods are duly tabulated, their adaptability to different climatic requirements are shown by reference to actual experiences in our own and other armies, and above all the necessity for occasional change in the best dietary lists is properly insisted upon. Naturally in this connection a great deal of attention is given to the various diseases associated with infected foods, notably to tuberculosis, trichinosis, tapeworm, anthrax, and the various toxin poisonings. A practical outcome to the discussion of this important subject is the following terse and emphatic statement of the author: "For field use no meat can take the place of bacon." This opinion accords with all the recent experiments which have gone to prove that pork in any of its forms is the most nourishing and sustaining of all the flesh meats.

The chapters on the selection of camp sites, their arrangement and sanitary management, are full of practical directions and are profusely illustrated. In fact the reader is easily induced to believe that with the modern simple and compact appliances for cooking, mess arrangements, and bestowal of garbage it is almost possible to adapt most of the modern hotel improvements to all the real necessities of tent or barrack life. It is eminently becoming for an American work to give the latest improvements in hospital construction, and the author meets the demand in a most effective manner by a detailed description of the best forms in use by our armies in comparison with the most approved constructions of other nations.

The disposal of excreta is a topic to which much serious attention is directed. The author discusses the fundamental principles of drainage from a very comprehensive standpoint. The different forms of primitive apparatus shown and their descriptions are studies in sanitary plumbing which cannot fail to fulfil every expectation of perfection of detail and adaptability of purpose. Indeed, to the ordinary camper-out, to the inhabitant of unsewered rural districts there is an amount of valuable information in this chapter which cannot be found in any truly sanitary work with which we are acquainted.

The prevention of disease in the soldier is the natural outcome and so-to-speak focal purpose of the book. And herein the author is thoroughly up to date in availing himself of all the recent observations connected with the more modern methods of disease propagation. The medical reader will be particularly interested in the admirable epitome of the present opinions regarding the rôles of the mosquito in the dissemination of yellow and malarial fevers. The literature on this subject is so voluminous and the statements of authors are in some respects so contradictory that it is refreshing to obtain a clear and unprejudiced view of the situation. While our author very properly acknowledges that the pestiferous insect is undoubtedly the host of the malarial parasite and the propagator of yellow-fever infection, he is somewhat loathe to believe, and we think with some reason, that neither the Culex species on the one hand nor the Anopheles on the other is absolutely the only agency of the respective infections.

The work is profusely illustrated and contains eight full-page plates. Although it is specially intended for army use and has been adopted as the official book of reference by the Secretary of War, Commander of the Army, and the Surgeon-General's Department, it will be found an invaluable addition to every medical library, inasmuch as it deals with such general principles of hygiene, water and food supply, nutrition, drainage, sewage disposal, and disease propagation as are of the greatest practical value to the general physician in his responsible position as a ready adviser on all health matters.

Transactions of the Medical Society of the State of West Virginia, Held at Morgantown, May 9, 10, and 11, 1900; instituted April 10, 1867. Wheeling: 1900.

This volume contains the usual number of interesting papers and has a frontispiece portrait of R. W. Hazlett, A.M., M.D.

Flesh Foods, with Methods for their Chemical, Microscopical, and Bacteriological Examination. By C. Ainsworth Mitchell, B.A., F.S.C. London: Charles Griffin & Co., Limited. Philadelphia: J. B. Lippincott Company. 1900.

This is a very instructive book, dealing with the details of proper methods of examination of meat and allied flesh foods. Many interesting tables are given and various illustrations add to the value of the book. It seems adapted for those desiring detailed laboratory methods rather than for the practical every-day physician.

Introduction to the Study of Medicine. By G. H. Roger, Professor Extraordinary in the Faculty of Medicine of Paris, Member of the Biological Society, etc. Authorized translation by M. S. Gabriel, M.D., with additions by the author. New York: D. Appleton & Co. 1901.

This book contains just the rudiments requisite for a preliminary grasping of the problems so intricate and varied in the study of medicine. The translation is certainly a credit to the author. This book will appeal to the student and to the one looking for rudimentary knowledge.

The Mensuration and Capacity of the Female Bladder. By Guy L. Hunner, M.D., Assistant Resident Gynæcologist to the Johns Hopkins Hospital, and Irving P. Lyon, M.D.

A small brochure.

Anatomie Générale Appliquée à la Physiologie et à la Médecine. Par Xav. Bichat. Première Partie. Paris: G. Steinheil. 1900.

This paper-covered volume carries us to page 256 of a work which, when completed, will embrace all departments of applied anatomy. The first part comprises general considerations and the cellular and the nervous systems. The text is carefully prepared but without illustrations.

Handatlas der Anatomie des Menschen in 750 theils farbigen Abbildungen mit Text. Mit Unterstützung von Wilhelm His, bearbeitet von Werner Spalteholz. Dritter Band, i. Abtheilung. Leipzig: S. Hirzel. 1900.

This third fasciculus of the first part of this choice work on anatomy corresponds with those previously issued, and which were favorably mentioned in these columns. Many of the plates are colored sufficiently for the purpose of differentiating vessels and other tissue.

Vasectomy Relative to Prostatic Disorders and Catheter Life, and Report to the Thirteenth International Congress of Medicine (Paris, 1900) on Urethro-Stenosis. By Reginald Harrison, F.R.C.S. Eng. London: J. & A. Churchill. 1900.

This is a small collection of papers which appeared in *The Lancet* from August 5, 1899, to July 14, 1900, together with a report to the International Congress of Medicine, 1900, on urethrostenosis. There is also added a list of the author's works on surgical subjects.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

COLITIS—PATHOLOGICAL SOCIETY—DROPSY—BRITISH MEDICAL ASSOCIATION—PLAGUE DUTY AT THE CAPE—SIR W. CHURCH—A BLIND SURGEON'S LEGACY FOR THE BLIND—DEATHS OF OCTOGENARIANS.

LONDON, April 12, 1901.

We have heard a good deal of late years about colitis, and not a few have thought it was an old acquaintance with a new name. It seems to have been specially prevalent in the lunatic asylums, and the London county council appointed Drs. Mott and Durham to investigate it in those under their control. The result is a valuable report, from which it seems that most if not all of the cases of colitis have been dysentery. The true nature of the disease having thus been brought to light, the necessary precautions against its spread will no doubt forthwith be rigidly enforced. The report insists on the infectivity, and traces the infection from bed to bed in several instances, showing how it spread by direct communication. The reporters do not find that lunatics are specially liable to dysenteric diarrhœa or ulcerative colitis. In fact the staff and officials of the asylums had sometimes suffered. The spread of the disease among the patients was due to the non-recognition of its infectivity, to the overcrowding of dormitories on account of the pressure of fresh admissions, and to the difficulty of attaining complete personal cleanliness of some lunatics.

Isolation, disinfection of clothing, etc., and other measures must now be systematically enforced and the plague stayed. Something, too, must be done to prevent overcrowding, but surely that ought not to be the erection of more palatial buildings for paupers. Architects have been too much trusted and their work has tended to ruin ratepayers by its extravagance.

At the meeting of the Pathological Society on the 2d inst., the changes I mentioned in a former letter were duly adopted. There will be four sectional secretaries for the four departments of pathology, viz., (1) pathological anatomy and histology; (2) bacteriology; (3) experimental pathology; (4) chemical pathology. One general secretary will organize the whole work. There will be also four committees of the council, presided over by four vice-presidents corresponding with the four departments.

Professor Starling made a communication on the pathology of dropsy founded on some experiments on normal animals, as he had not been able so far to apply his views under diseased conditions. He defines dropsy as an abnormal accumulation of normal fluid in the tissues due to a disturbance of the balance between the production and absorption of fluid in the subcutaneous tissues and serous cavities of the body. He limited his remarks to the "mechanical form" of dropsy due to simple obstruction. Diminished absorption is a negligible factor, compared with transudation. It had been supposed that a rise of pressure in the veins and capillaries would explain dropsy, but obstruction to a vein in an animal does not produce œdema unless the vitality of the capillary walls be also lowered, as by the injection of a tissue poison. In cardiac dropsy it is difficult to see how there could be any increase of pressure in the capillaries, and Professor Starling's experiments showed him that there was really a fall of pressure. The prime change must consequently be in the walls of the capillaries. It was easy, too, to produce pleurisy by slight damage to the membrane or capillary walls, but he could not in various experiments do so by a rise in capillary pressure. In ascites pressure had more influence, as in cardiac disease there was a rise of the blood pressure in the liver, and lymph was exuded into the peritoneum. After exposure of intestine, exudation occurred on account of injury to the capillary walls.

Dr. Lazarus-Barlow said that he had raised the blood pressure of a dog's leg for five or six hours without producing the least dropsy. He believed that the two factors in the production of dropsy were starvation of the tissues and their poisoning by waste products. When a tissue was functioning, its vessels dilated and there was an increased flow of lymph. Dr. Barlow thought that in dropsy there was an excess of this normal process. In his view, therefore, the tissues rather than the vessels determined the occurrence of dropsy, though no doubt in most cases the process became complicated. This view he said was the best working hypothesis, for it explained more varieties of dropsy than any and indicated the lines of treatment likely to be of use.

Dr. Ewart thought a nervous factor must be present, especially in local œdema.

Dr. Sherrington said the vessel wall was the one constant element which seemed to justify the inference that it was the chief seat of change.

Dr. Newton Pitt asked why there was no œdema but ascites in mitral stenosis, while in mitral incompetence the reverse was seen. Perhaps Professor Starling's observation on the liability of the liver might be a clew to this. The late Dr. Wooldridge attributed the main cause to blood change.

Dr. Herringham said we could not altogether ignore mechanical forces. In general dropsy the side on which the patient lay was the one to swell.

Dr. H. White said effusion was not rapid when the portal vein was compressed by tumors. Effusion was most rapid in chronic peritonitis when the membrane was damaged.

Dr. Bradford regarded œdema of the legs in ascitic cases as the result of slight constriction of the inferior vena cava.

Professor Starling in reply said ligaturing the portal vein produced intense congestion of the intestines but no ascites. The rise of pressure therefore could not be the essential factor. Urticaria could be produced in the dog by injecting extracts of shell fish. He had repeated the late Dr. Wooldridge's experiments but had come to conclusions opposite to those of the latter.

The branches of the British Medical Association are holding meetings to consider the proposals for reorganization made by the committee appointed last year. You may remember that the growing discontent with the council's procedures led to repeated protests at the annual meetings. These meetings were generally so managed that expressions of opinion which did not accord with those of the council were easily burked, and when that could not be manœuvred were quietly ignored. At last the demands for reform were so determined that something had to be done and this committee was appointed. Their report extends to forty-eight pages the size of the *Journal*, and has given rise to some correspondence in its columns as well as to the criticisms of the branches. The most important proposal perhaps is to introduce the principle of delegation. Meetings of delegates are to be held and would, of course, to some extent, but not altogether, supersede the council. The council had its own supporters on the committee and are not inclined to part with their powers; so it is provided that no financial resolution of the delegates shall take effect without the approval of the council. In fact careful scrutiny of the report seems to suggest that the use of the delegates' meeting will be to take the onus of any act the association disapproves and to propose anything the council would like—a sort of buffer between the council which will retain all its power and those members who are dissatisfied with it. Constitution making on paper is a rather unprofitable employment, though it may serve as an amusement for idle hours. It is quite likely this elaborate attempt will eventuate in nothing. I hear that an attendance of four members in one branch was the result of the summons to consider it, while at another only one man put in an appearance. In other cases four and five per cent. of the members talked the matter over. It would probably be the same with delegates, but it is proposed to pay them and the cost of doing so would be serious. Another proposal is to compel all members to be attached to a branch and pay the extra subscription. Already protests against this are heard, and if carried out the change may cause a great loss of members. A power of referendum is also reserved to the council as against the delegates, as well as the financial disability. It is not easy to say of what use the delegates are intended to be, or to foresee what would be the effect of the change. They could certainly serve to let off some of the talk and to shelter the council from censure at times, but division of responsibility is apt to prove dangerous. The association is registered as a limited liability company. The council are the directors. The members meet only once a year. If they met more frequently and voting papers were introduced, perhaps that would answer all the purposes of delegates and satisfy reformers. There are some other points but they are of minor interest. What seems a strange hope entertained by the committee is, that they will be able by these changes to make the members generally take a real interest in the association and induce them all to vote. Not even in the parliamentary election can all voters be brought to the poll.

Half a dozen doctors are being sent out to the Cape for plague duty—a significant comment on the policy of ignoring the outbreak when first it occurred.

Sir William Church has been re-elected president of the Royal College of Physicians.

Mr. George Seale, who retired from practice in 1872 on account of glaucoma, has left £20,000 to provide annuities for blind persons who are in need.

Among recent deaths are four octogenarians: Dr. Dane, C.B., aged eighty-seven years, Dr. Thomas Morris, aged eighty-three years, Dr. Durrant, J.P., aged eighty-seven years, and Dr. Sykes, J.P., aged eighty-four years.

OPERATION FOR HERNIA IN CHILDREN.

To the Editor of the Medical Record.

Sir: Having my attention called to-day to "Surgical Diagnosis" I happened to see in MacDonald's work of 1898, on page 263, that operation for hernia was contraindicated in children under six years of age. In reply I would say that I have operated upon three boys (all on the left side) of less than four years of age. One heruia had been following the testicle into the scrotum, the others from the external ring. The last boy operated upon is now eleven years old, all perfect. Boiling water was my antiseptic.

George H. Fox, M.D.

Janesville, Wis.

WHY NOT BE FRANK WITH THE PUBLIC?

To the Editor of the Medical Record.

Sir: Much is being said nowadays concerning the relation of the public to the medical profession, and the secret of power in Christian science and kindred delusions. There is one aspect of this question to which I have not as yet seen reference made. It long ago struck me that the medical profession has itself partly to thank that the laity are attracted to these various forms of suggestion therapy as to something new. The profession has not been candid with the public. Doctors know that a vast deal of the medicinal treatment which is asked of them, and which they give for a consideration, is needless. This applies not so much to the surgeon or diagnostician as to the general practitioner. To him come the host of the vaguely suffering; the people who don't know how to live, and resent instruction; the functionally disturbed, the neurotics, and *malades imaginaires*. Experience and tradition have led them to expect medication from medical men. They get it, it fails, and they drift, perhaps bringing up at Christian science or one of its congeners. Persuaded to forget or ignore sensations, their shackles fall off, and they discover that they never needed medicines at all. Then one of three inferences is inevitable: Either the doctors knew the patients did not need drugs, in which case it was fraud to prescribe and receive money for them; or, they did not know it, and were ignoramnses; or, the special form of suggestion by which the patient has found relief is a great and precious discovery, a revelation, outside the ken of a bigoted medical profession.

Now, had physicians when able to make out the character of these cases been absolutely candid with them, had they refrained from medication even by placebos, and frankly explained the nature of the trouble and urged the patient to forget it, and look out and not in, at least the profession would not stand humiliated as it does in the eyes of so many at the present day.

In the face of the good they are doing it is quite useless to call these various types of auto-suggestion delusions. A host of witnesses will rise up and reply: "Whereas once we were invalids while taking drugs, now we take no drugs and are well." To explain the benefit obtained as suggestion does not rescue us from the position of having for years needlessly dosed these patients, neurotic, hypochondriacal, hysterical, call them what you like, when all they really needed was to be taught self-forgetfulness.

Our profession has been wallowing in a slough of excessive drug-giving these many years. A strange and seemingly instinctive wisdom has actuated the popular insurrections against canonical therapeutics. Hahnemann led one. From homœopathy the public (and the regular profession as well) learned not only that nauseous doses and indiscriminate bleedings and purgings were needless, even injurious, perhaps homicidal; but that many ailments subsided of themselves under water drops. That movement was a great eye-opener, but it did not go far enough. And to-day the Christian scientist is telling our public that not even water is needed; that faith, or prayer, or mental attitude suffices. Hahnemann surprised the doctors as much as the laity. The results of Christian science do not surprise physicians of this day at all. They knew all about auto-suggestion before. Indeed the educated medical man is prepared to go much farther than Christian science. For if he spoke fully and candidly he would say: "You need neither drugs nor water drops nor prayer. All you need is to disregard sensations, live right, and forget yourselves." Why, then, does he nòt do this?

One reason, and usually the first, that I have heard advanced in justification has been that unless we satisfy the patient's craving for medicines, even though not clearly indicated, he would seek satisfaction elsewhere and wander to some less discerning or less conscientious rival. If this reasoning were made public, it might remind an unsympathetic laity of the ancient robber's plea that the traveller is sure to be fleeced farther on, and so may as well give over first as last.

Others say in effect: "The interests of the patient demand that he have a skilled physician. If dissatisfied with myself, the 'skilled physician' of the major premise, he may pass to the care of the unskilful and unscrupulous. Then, if he fall really ill, he will suffer for his folly. Better for his own sake, therefore, that I retain my hold upon him, so that I may be there to help him when he really needs aid." Probably few put the matter thus jesuitically, yet in one form or another I fancy this argument affects many minds that would spurn the idea of doing evil that good may come.

Most men state the case in this way: We are not doing evil. The patient puts himself in our hands. We cannot without giving offence be candid with him or her (especially her); for if there is one thing the laity won't stand it is candor about their ailments. We must take these cases at their own valuation, administer remedies or placebos as our judgment dictates, and if we fail, we have done our best.

The point I am raising is, of course, whether this plan is the best.

No one rejoices more keenly than the writer in the advances all along the line of our great calling. No one sees more clearly the public danger of extending systems of auto-suggestion to ills other than the vaguely nervous or functional; nor agrees more heartily in the need of requiring all practitioners of healing, under whatever guise, to give proof of knowledge, lest faith-cure be applied to diphtheria, for example. Yet the results obtained by systems of self-persuasion, so ingeniously adapted to the needs of the weak-kneed and unstable, may well cause us to examine our own methods carefully, to let no casuistry or veiled self-interest mislead us into virtual dishonesty, and to meet the public candidly and openly as the best means of silencing invidious comment upon medicine as now practised.

However, it is to elicit rather than to express opinions that this letter is written. And to avoid intruding his own personality into the discussion, lest his shortcomings distract attention from its importance; or, worse than all, lest he appear to any of his brethren to say between the lines "I am holier than thou," the writer begs to subscribe himself, Yours,

X.

ON FAITH CURES.

To the Editor of the Medical Record.

Sir: In the Medical Record for April 20, 1901, Dr. Huber deals with the question of faith cure in a concise and comprehensive way, but there are one or two points that seem to me to be of considerable importance that I would like to add. Adult Christian scientists are mostly people with degeneration or disease of the generative organs. If the fact is not generally known, physicians will have little difficulty in corroborating the statement by reference to their notes of cases; and this interesting fact simply falls into line with our previous knowledge on the relation between derangements of the generative organs and the mental habit of the individual. The followers of osteopathy represent a very different class, made up largely of people of quite normal minds. They become impressed by the good results of osteopathic treatment which are patent to all of us, but sooner or later come to recognize the fact that the practice of osteopathy is based upon fraud, and that its practitioners when intelligent men are shrewd charlatans. We can safely depend upon the observant patient soon to classify osteopathy properly, but not so with Christian science, which represents one of the psychopathic epidemics that sweep across the country from time to time. The primitive form of this sort of epidemic is illustrated in the school-room when the teacher yawns and sets half the class to yawning. A more marked demonstration occurs when an hysterical girl laughs uncontrollably and gets so many other girls to laughing in the same way that it becomes necessary to close the school. The most impressive influence of suggestion is seen when an adult hysteric with some fanciful mission engages the interest of so many others who have the same form of nervous derangement, that the movement gains great momentum and causes some fairly well-balanced minds to topple over and fall into it. That is what is now occurring in the sweep of Eddyism.

If we did not have much healing by suggestion in the days of Christ, the conditions were at least most favorable for such healing at that time, and many of the miracles as reported would seem to have been in no way different from the healing miracles of Schlatter and of Carol Norton. Renan tells us that the Greek and Roman savants looked upon the healing miracles of Christ precisely as we look upon those of Norton to-day (Renan, "Vie de Jésus," chap. xvi.). This in no way detracts from the beauty of that perfect life which is the inspiration of all Christian people. The curing by relics in the Catholic Church is one of the most persistent examples of the influence of suggestion. I say this with no feeling of disrespect.

Many members of the Catholic clergy are my personal friends—earnest and sincere men whose lives are devoted to good works and who would be unwilling to deceive, but they are not trained in methods of scientific investigation, and they do not follow up the reports of cures for purposes of accurate record. Most of the cures by relics are symptomatic cures of temporary duration, in hysterics, or in people who are not able to supplant superstition by knowledge. We see much suffering resulting when patients with actual disease, and moved by emotional excitement, throw away crutches and orthopædic apparatus, for instance, which they can ill afford to buy again a few days later. It would seem to be greatly to the credit of the Catholic Church if it could do away with what physicians know to be false cures by faith—the same cures that are made daily by Dowieites, Weltmerites, clairvoyants, esoteric vibrationists, occultists, magnetic healers, phrenopathists, viticulturists, venopathists, psychic scientists, and some twenty other cults that are flourishing in America to-day. It was testified last year in Missouri that Weltmer alone employed sixty-five stenographers to attend to his absent-treatment business. It is not difficult to make use of human credulity for selfish purposes of personal gain, and it is to the glory of the regular medical profession that its younger members who know how to deceive people prefer to starve rather than take up methods like Christian science that would immediately yield a large income.

Mrs. Eddy says: "I healed consumption in its last stages, the lungs being mostly consumed." "I healed carious bones which could be dented with the finger; I healed them while the doctors were preparing their instruments for operation." "I healed in one visit a cancer that had so eaten the flesh of the neck as to expose the jugular vein so that it stood out like a cord." These statements are by no means ordinary falsehoods. They are simply the statements that we might expect from an hysteric, and represent mental derangement—pathological misstatement. Physicians present their cured cases for investigation, but the Christian scientists cannot give us corroboration of their statements. It would be dealing with material things to show a case that had been cured of cancer. When Mrs. Lathrop, with her charming presence of manner, told us at Albany of the things of which she had been cured, every physician who was present at once recognized the typical tale of an hysteric; but it impressed some of the legislators who were not familiar with such cases. Physicians make mistakes with hysterics unless they are constantly on guard. Not long ago I operated upon a supposed case of appendicitis in which the young lady spoke her piece perfectly, and gave me not only a faultless history of subjective symptoms, but presented a rigid abdominal wall. On opening the abdomen I found the appendix and peritoneum perfectly normal and did not remove the appendix. She was cured of appendicitis symptoms at once. She was operated upon at Buffalo about a year later, and the appendix was incidentally found to be still normal. The patient was an hysteric and would undoubtedly have been cured as promptly by faith as she was by operation—to the advertising credit of the healer. I have traced several cases of Christian-science cures and have found all but one to have been in hysterics. This one was another case in which I erred in diagnosis. The case was one of abdominal lesion, and on opening the abdomen I found what appeared to be malignant papilloma of the peritoneum with universal adhesions. I gave a hopeless prognosis. The patient was taken in hand by Christian scientists and in a few months was cured. On hearing of the cure I submitted for pathological examination a specimen that had been preserved in alcohol from the omentum of the patient, and the case was determined to have been apparently one of tuberculosis of the peritoneum. It was cured in the way that is familiar to all of us, by the simple exposure of the peritoneum. The Christian scientists made much capital of this case. This is the only case of actual disease coming under my observation in which a cure was made by faith, but I have seen several curable cases of actual disease that went on to disaster because they were under the care of Christian scientists. This psychopathic epidemic of Christian science would ordinarily have come to its end slowly, but the promoters of the cult have sought legislative protection, and this has caused so much discussion and such a tremendous flocking to the fanciful cause that it will probably fall by its own weight within the next two years, and some other similar epidemic will take its place. One cannot well appreciate the overpowering influence of the present epidemic unless he has been in legislative halls and has seen the frightened legislators hovering between reason and promised votes. The incident will in all probability be very beneficial in its results by causing closer union in the ranks of the medical profession, and the student of sociology will again see the working of the law of compensation which eventuates in good for the public no matter what dangers seem to be impending.

Promoters of various fanciful healing methods are fond of quoting the names of judges and of senators who have become adherents to their doctrines, and this carries great weight with the laity. We need to answer the argument simply by saying that a still larger number of judges and senators are at present being cared for at asylums.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Annual Meeting, April 15, 1901.

Parker Syms, M.D., President.

Adenoma Sebaceum.—Dr. William S. Gottheil presented this specimen. The tumor consisted of an immense hypertrophy of the sebaceous glands. The tumor itself was a rare form of adenoma, occurring as an isolated growth, most often on the scalp.

Nævus Unius Lateris.—Dr. Gottheil also presented a patient with such a growth. This occupied the entire right axilla in a boy of ten years, was black, and had linear excrescences along the posterior margin and down the forearm. The microscope showed this growth to be largely a papillary hypertrophy with increase of blood-vessels—in other words, a true nævus.

Sarcoma Cutis.—Dr. Gottheil presented two patients with this condition. Both were men well advanced in years. Their lower extremities showed particularly well the numerous dark, hard nodules so characteristic of this condition. Microscopical examination showed the growths to consist of a round and spindle cell infiltration of the corium, but without evidence of tuberculosis. In a number of cases reported, excellent results had followed the use of heroic doses of arsenic injected hypodermically. Under proper treatment the prognosis was good; if not so treated, internal metastases and death would result.

The Diagnosis and Surgical Treatment of Prolapsed Kidney, with a Demonstration of a Simple Method of Examination for its Detection.—Dr. Augustin H. Goelet read a paper with this title. He said that his experience had taught him that prolapsed kidney was much more frequent than was generally supposed, and that it was not suspected because it often gave rise to no symptoms directly referable to the kidney. The condition was often overlooked because of defective methods of examination. He had found palliative methods of no avail, and thought lumbar fixation the only proper treatment when the symptoms were such as to demand interference. Prolapsed kidney could be found in about one out of four or five gynæcological cases coming under observation. Of this number about fifty per cent. suffered from this change of position of the kidney, and about half of these experienced a fair degree of relief from the use of a properly fitting bandage. Floating kidney was always congenital; prolapsed kidney was always acquired. The right was more often prolapsed than the left. Both kidneys were depressed nearly half an inch on deep inspiration. The causes of the condition were largely a matter of conjecture. The chief symptoms were persistent intestinal distention, gastric irritability, insomnia, unusual fatigue on exertion, dragging pains in the loins, irritability of the bladder, more pronounced during the day and after standing or walking, acute attacks of pain resembling those of renal colic. In the examination for prolapsed kidney it was best to have the patient standing, and the body slightly forward. The patient should stand firmly against a

wall or table, with no backward inclination of the body. The patient was then directed to take several deep inspirations while the operator grasped the loin just below the ribs with the thumb and fingers of the left hand and made deep and upward pressure in the right iliac fossa with the fingers of the other hand. In this way if the kidney was prolapsed it was pushed forward by the right hand against the left thumb. If the kidney was not felt, the patient should be directed to cough. The thumb should not be relaxed while the right hand was making pressure. To avoid any interference with the sense of touch the skin should be pulled downward before the examination was made. Prolapsed kidney was most often mistaken for a distended gall bladder. The chief distinctions were the mobility of the kidney and the tenderness of the gall bladder. Tumors of the omentum in this situation were nearly always associated with malignant disease elsewhere. Impacted fæces might be mistaken for a prolapsed kidney. The operation for fixation of the kidney was comparatively safe, and was not mutilating; moreover, it yielded very satisfactory results. The operation was best done with the patient in the Sims position. The patient should be confined to bed for three weeks, the sutures being removed at the end of a fortnight. While in bed the patient should be kept in the recumbent position, and if turned on the side it should be on the side operated upon in order to prevent dragging upon the sutures.

Dr. George Tucker Harrison spoke of the difficulties of diagnosis, and declared that many disappointments would be met with, even though the method of Dr. Goelet were used, unless ether narcosis were also called to one's aid. The knee-chest position was also an aid. He warned against too much enthusiasm in the matter of operating upon supposed prolapsed kidneys.

Dr. Heinrich Stern said that since October, 1900, he had examined 854 new cases at his clinics. Of these 351 were in males and 503 in females. Of the males 284 had been examined for disease and displacement of the kidneys, and 17 instances of prolapsed kidney, all on the right side, or 6 per cent., had been detected. Of the 503 women 418 had been examined as to the condition and position of their kidneys. In 76 nephroptosis had been demonstrated, or 16 per cent. In 69 cases the right kidney had been dislocated; in 5 the left kidney alone, and in 2 cases both kidneys had been prolapsed and completely palpable. The discrepancy between his figures for males and those of others seemed to be because he calculated from cases actually examined, while other statistics were based on the total number treated. He was on principle opposed to surgical interference with the kidney, and believed that only when imminent danger demanded it, was an operative procedure justified. In hydronephrosis, for instance, when a ureter was strangulated, an operation was indicated. The best medicine for the fixation of a movable kidney was rest. Rest in bed was the desideratum; bandages accomplished this to some extent. Massage and similar treatment were contraindicated. One should endeavor to stimulate the formation of intra-abdominal fat deposits, and this was best done by rest. In his opinion, the equilibrium of the abdominal organ could be best established by the production of a condition of healthy obesity. He was opposed to operative interference, because he knew that at least thirty-three per cent. of the operated cases were failures. The same percentage of failures might be recorded by the more conservative medical treatment. The operation must be useless, as a prolapsed kidney was only one of the displaced organs of a general enteroptosis, and an operation on one organ certainly did not ameliorate the state of general enteroptosis.

Dr. J. Riddle Goffe said that he had used for some years the method of examination recommended in the paper, having first learned it from Dr. George M. Edebohls. As regarded the method of operating, he said that those who had had the largest experience in these operations were in favor of bringing the substance of the kidney directly in contact with the muscle. To bring the kidney into the wound he found it most satisfactory to make pressure from below with an air cushion.

Dr. Goelet closed the discussion. He said that from conversation with Dr. Edebohls he was under the impression that the method employed by the latter was quite different from that described in the paper. So far as he knew, the method had originated with himself. His results had been just as good in the cases in which he had not opened the capsule.

Officers Elected.—*President*, Dr. Parker Syms; *First Vice-President*, Dr. Alexander Lambert; *Second Vice-President*, Dr. Francis W. Murray; *Secretary*, Dr. Ogden C. Ludlow; *Corresponding Secretary*, Dr. M. L. Maduro; *Treasurer*, Dr. Charles E. Denison; *Member of Executive Committee*, Dr. Charles S. Benedict.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 22, 1901.

George B. Fowler, M.D., President.

Supports for Symptomatic Movable Kidney.—Dr. George M. Edebohls discussed this subject (see page 690).

Dr. A. Rose said that he had made extensive use of adhesive plaster as a mechanical support in cases of gastroptosis, and had usually found that, after it had been worn for a few weeks, not only had the gastroptosis been relieved, but the movable kidney remained in its proper place. He had known the kidney to be in position six months after the plaster had been removed. It was difficult in practice to fit an efficient bandage satisfactorily to lean persons. The adhesive plaster in these cases bore the same relation to the ordinary elastic bandage that plaster of Paris did to ordinary splints in the treatment of fractures and dislocations. He had noted that the patients in whom the kidney had remained in place had been those who had gained in weight while wearing the adhesive plaster. While the operation for fixation was certainly indicated in some cases, he was sure there were many in which great relief would result from the use of the adhesive plaster.

Dr. Edebohls said that he had not made use of adhesive plaster in these cases, yet he thought well of it, especially when there was an associated enteroptosis. According to his observations and those of Glénard, movable kidney often existed without enteroptosis.

A Plea for the Conservation of Breast Milk Either in Whole or in Part.—Dr. Thomas S. Southworth read a paper with this title (see page 686).

Dr. H. Koplik said that it was a common experience for infants to be put on the bottle when only a week or two old, simply because the mother's breast was caked or the supply of milk was rather scanty. It was the duty of every physician to make a conscientious effort to coax the breasts into the secretion of a moderately good supply of milk. He had presented a communication to the American Pediatric Society three years ago, emphasizing the importance of resorting to supplementary feedings. Of course, if the supply of breast milk was sufficient, no such feedings should be allowed. If the breasts would secrete enough for only three or four feedings daily, it was well worth while to try to keep the milk in the breasts.

Dr. E. B. Cragin emphasized the importance of insisting upon regular habits of nursing from the very beginning. A case was cited in which, by massage of the breasts every four hours, and the use of a strong child to suckle them for two or three days, a sufficient supply of milk had been secreted to allow thereafter of the mother nursing her own child at intervals of two hours.

Cleft Palate and its Association with Harelip.—Dr. John H. Branth read this paper. He called attention to the experience at various zoological gardens to the effect that the offspring of lions fed on meat with large bones were apt to have cleft palate, while this was not observed when the animals were fed upon meat with small bones. The author then reviewed at length the anatomy of the parts involved in these operations, and the different varieties of harelip and cleft palate. Infants so deformed could not, of course, suckle at the breast, and must be fed with a spoon. The operation should not be done when the general condition of the patient or any other reason made it improbable that primary union could be secured. When the intermaxillary bone projected forward, he preferred to wait until the incisors had been cut before he operated, yet the operation should not be deferred longer than the age of two years. It had been his experience that in the large majority of patients only a few of the sutures inserted at any one operation held. Two patients were presented to show what could be done by persistently operating, gaining a little each time. The hemorrhage at the operation was usually controlled without difficulty. It was well to give the patient belladonna or atropine to reduce the troublesome flow of saliva. Thumb forceps must not be used in these operations, because the pressure which they exerted caused points of sloughing. The tension on the sutures should be moderate. In the soft palate lateral punctures would reduce this tension and keep it within proper limits. The speaker advised that the palate operation be made the first, although this was contrary to the usual teaching. From four to six weeks should elapse between the operation on the palate and that on the harelip. Dr. Branth said that he took special care in his harelip operations not to have any angles in his incisions, and so to plan them that the lines of union corresponded with the normal facial lines. He made use of chromicized catgut for all sutures in both the harelip and the palate operations. Harelip pins should be relegated to the past. Liquid food should be administered after operations, and the hands should be secured so as to prevent injury to the field of operation. The child should be taken into the open air a few days after the operation.

Dr. W. P. Worster said that the paper presented a number of important and novel points. One of the most novel of these was the removal of the whole vomer. Some of the English surgeons had attempted to make a "V," but the removal of the vomer was much better, as it relaxed the whole palate and greatly aided in securing good coaptation. The author's plan of doing the palate operation first also seemed to him to be an improvement. He had found that the use of a very strong salt solution almost completely checked the hemorrhage attendant upon these operations.

Dr. G. Lenox Curtis accepted the suggestion that the palate operation should be done first, but added that this rule might be deviated from in cases in which life depended upon nursing, or when competent surgical assistance was not at hand. It was surprising how much could be accomplished by the use of a properly fitted obturator. If the muscles were brought early into apposition, they developed instead of undergoing atrophy. When the operation was done in early infancy, there was much less deformity. If the operation was delayed until faulty habits had been formed, the latter were overcome only with difficulty. The author's method of disposing of the vomer simplified the operation and yielded satisfactory results.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, April 25, 1901.

A. Brothers, M.D., Chairman.

Post-Mortem Cæsarean Section, with Specimen.—Dr. S. Marx presented a uterus containing a placenta, which was prævia. It had been taken from a multipara who, up to six weeks ago, had been in perfect health. Then, when about six months pregnant, a slight uterine hemorrhage occurred, and from this time on the bleeding had continued until she had become very much exsanguinated. Nothing had been done for her in the way of treatment. She had suddenly had a rather more profuse bleeding, and had fainted. On visiting the case he had found her in the deepest collapse, and had consequently refused to interfere actively. Preparations had been made to infuse the woman, but before they could be instituted she suddenly expired. Fœtal heart tones being heard, he had at once opened the abdomen and delivered a living child, but it had lived only a few minutes. The uterus had then been extirpated and the placenta found implanted marginally and separated from the lower uterine zone over an area whose diameter was about two inches. The amount of blood lost immediately preceding the death of the patient had been small, certainly not more than two handfuls, but it had been sufficient to cause death in this already very anæmic woman. The lesson which this case taught was evident, *i.e.*, as soon as a diagnosis of placenta prævia was made or even suspected, the uterus should be emptied at once.

Cystic Papilloma of the Ovary.—Dr. H. N. Vineberg presented three rare ovarian tumors. The first was a cystic papilloma of the ovary, removed from a widow, fifty-six years of age, in whom the menopause had been established two years and a half previously. After the cessation of the menses, there had been a slight bloody discharge at intervals for over six months. The woman, who had long been a sufferer from flatulent dyspepsia, had begun to lose weight, but this had become specially noticeable in the last six weeks before coming under observation, during which time she had lost eighteen pounds. A few evenings before coming to Dr. Vineberg she had been seized with severe cramp-like pains in the abdomen. When first seen, she had had a pulse of 120 and a temperature of 101° F., and there had been a semi-elastic, non-sensitive, movable tumor in the abdomen, reaching nearly up to the umbilicus. Vaginal examination had revealed a hard, globular mass and some nodules on the surface of the tumor. There was a strong family history of malignancy. On August 26, 1900, he had done an exploratory laparotomy, and this had revealed a cystic papilloma of the right ovary. The cyst contained puriform fluid. Recovery was uneventful.

Myxosarcoma of the Ovary.—The second specimen was from an unmarried woman twenty-six years of age, who had been in very poor physical condition when first seen. She had been regular in her menstruation up to three years before, when, as a result of mental shock, there had been an interruption for a time. It had subsequently become regular, but nine months before she came under observation the abdomen had be-

gun to enlarge. On examination, the abdomen had been found enormously distended with free ascitic fluid, and in the lower part a mass about the size of a fœtal head. He had made a diagnosis of a solid tumor of the ovary, with a possible metastasis of the peritoneum. On operation, he had found a tumor of the ovary with a twist of the pedicle of 180°. Microscopical examination showed the growth to be a myxosarcoma of the ovary. The patient had made a good recovery.

Papillomatous Cyst of the Ovary.—The third case was one of papillomatous cyst of the ovary, and the specimen had been removed from a woman thirty-six years of age. Two years previously a physician had made out a small cyst of the ovary. At the time of coming under his observation it was growing very rapidly. He had removed the tumor, and the prognosis seemed to be very good.

Tumor with Four Twists in the Pedicle.—Dr. H. J. Boldt said that a woman about seventy years of age had recently come under his care. On account of dyspnœa, extensive bronchitis, and poor heart action the operation had been done under subarachnoidean anæsthesia induced by the injection of ℥ xx. of a two-per-cent. solution of cocaine. The anæsthesia had been perfect. During the endeavor to extirpate the tumor a rent had been made in it, and this had allowed the escape of a quantity of material which, though without odor, resembled fæces. He had found in the pedicle of the tumor four distinct twists from right to left. So far as he knew, this was the only case on record in which there had been four twists observed in a pedicle. The patient had rallied well from the operation, and was now doing well.

Pregnancy Complicated by Fibroids.—Dr. Boldt also exhibited a specimen taken from a woman who had come to him in the fourth month of pregnancy. On operation, he had discovered several fibroids, and one large one with twists in the pedicle. The large tumor he had removed.

Dr. Vineberg said that some years ago he had operated in a case in which there had been three twists and a half of the pedicle, associated with urgent symptoms. When the abdomen was opened, the cyst wall was almost black, and there was some peritonitis. He had removed the tumor under anæsthesia with nitrous oxide and ether, and the patient had made a good recovery.

Dr. E. H. Grandin said that the practical deduction to be drawn from these cases was that any woman who was known to have an ovarian cystoma, and who presented symptoms of great distress in the abdomen, should be operated upon as soon as possible, as these were the symptoms of twisting of the pedicle. If operation was not promptly done, the case was likely to terminate fatally.

Dilatation of the Cervix.—Dr. Henry J. Garrigues read this paper. He said that dilatation of the cervix was most often demanded during labor because of placenta prævia, eclampsia, or threatened death of the fœtus. When dilatation was slow and imperfect in other cases, it was usually because of mechanical obstruction. To favor dilatation of the cervix, one might inject into the cervix gr. $\frac{1}{4}\frac{1}{0}$ of atropine dissolved in sterilized water, or the cervix might be painted with a ten-per-cent. solution of cocaine. Other useful medicinal methods of aiding dilatation consisted in administering gr. xv. of chloral every twenty minutes for three or four doses, or antipyrin gr. x. every half-hour for three doses. Among the mechanical methods of securing dilatation a good one was to insert a strip of iodoform gauze into the cervical canal as far as possible, and to pack the vagina with the same material, or with gauze wrung out in a ten-per-cent. solution of creolin. The next day the packing should be removed, and it would then usually be found that it could be inserted farther into the cervical canal. When rapid dilatation was demanded, manual dilatation could be employed, and would be found exceedingly useful. First one finger, then two, three, and four fingers, and finally the whole hand should be introduced in the shape of a cone. Braun's colpeurynter acted slowly. Barnes' cervical dilators were excellent as far as they went, but the largest dilatation secured by them was an opening two and one-quarter inches in diameter. These instruments had the disadvantage of favoring prolapse of the umbilical cord and of pushing the presenting part away. Lateral pressure was to be preferred to pushing upward of a large conical mass. The making of multiple small incisions in the cervix was an old method of overcoming its rigidity. Three or four deep incisions, which divided the whole vaginal vault as far as the vaginal junction, had become widely known through their advocacy by Dührssen. The cervix should be seized with two pair of bullet forceps, and the cut made between them. It was of service only when the cervix was obliterated but the os was not fully dilated. The danger of infection was, of course, increased by this procedure. The incisions might not heal well afterward, and, in spite of their length, the tear might extend into the parametrium. It was better to close these incisions by suture immediately afterward. These deep incisions might save a child's life that would otherwise be lost, but they exposed the mother to immediate danger and remote suffering.

Axis-Traction Forceps.—Dr. Egbert H. Grandin read a paper on this subject (see page 694).

Version: Indication, Limitation, and Technique.—Dr. S. Marx read this paper (see page 692).

Symphyseotomy.—Dr. Edward A. Ayers was the author of this paper. He said that he had performed symphyseotomy thirteen times on eleven individuals. In a service of about five thousand confinements he estimated that there had been about twenty-five cases which would have been suitable for symphyseotomy from a theoretical standpoint had they been reached at the proper stage to justify this operation. These thirteen operations had been done without infection of the joint and without a death attributable to the operation. Hemorrhage had not amounted to more than three or four ounces in any case. No sutures had been inserted, and no general disability had ensued in any case. A well-defined prejudice seemed to exist against symphyseotomy, partly owing to the fact that most patients had been subjected to severe efforts at forceps delivery before the symphyseotomy, and the operators had had almost no experience with the latter operation. He believed that perfect technique and asepsis could be obtained by his method of subcutaneous section at the symphysis. It was much easier to secure perfect asepsis here than in a Cæsarean section. A separation of more than two inches and a half should not be counted upon. It was very important to secure full antepartum dilatation of the cervix before operation. One reason for this was that in symphyseotomy cases the tendency of the cervix, anterior vaginal wall, and bladder to prolapse was very much greater than under ordinary circumstances. Moreover, the mechanism of delivery of the head was somewhat disturbed by the separation of the symphysis. Injury to the sacro-iliac joint need not occur. The natural tendency was to good union at the symphysis, and this became a certainty under an intelligent and skilful after-treatment. He was convinced that such union could be best secured by slinging the pelvis in a U-shaped hammock. If he believed that sutures were a necessity in symphyseotomy, he would discard the operation in all cases in favor of Cæsarean section. The test for the adaptability of symphyseotomy

to the individual case should be made during labor, and while the patient was anæsthetized, because only a few minutes were required to prepare for this operation. The great majority of cases of pelvic contraction lying beyond the scope of the forceps could be delivered by symphyseotomy.

Cæsarean Section.—Dr. E. B. Cragin read this paper (see page 695).

Dr. Charles Jewett said that, while the local use of atropine seemed rational as a means of aiding dilatation of the cervix, he had never tried it. Instead, he had sometimes made use of a dose of opium, and with very satisfactory results. Manual dilatation should be resorted to only in cases in which rapid delivery was indicated. When it became necessary to deliver the fœtus in the first two or three months of pregnancy, it had been his custom to dilate the cervix only a little, and then to use a forceps and a curette for the removal of the ovum through a small opening. Version was an operation which had been too much neglected; nevertheless, he had not always refrained from the use of the forceps when the head was above the brim, provided he could readily crowd the head into the brim and hold it there during the application of the axis-traction forceps. He felt compelled to differ from Dr. Ayers on his method of performing symphyseotomy as well on his selection of this operation. The open wound for symphyseotomy seemed to him to possess advantages which must be obvious to all surgeons. He had done eight symphyseotomies, and the results had been entirely satisfactory. One patient had died from œdema of the lung, which had not had anything to do with the operation. He had not been able to follow all these cases for any great length of time, and he had felt some misgivings lest the operation of symphyseotomy might subsequently cause trouble with the bladder from the loss of the natural supports. He had not done the operation in any case in which the true conjugate had been less than three inches, because this limit seemed to him to afford a necessary margin to make up for the errors incident to pelvimetry. The field for symphyseotomy was a very small one. The results from Cæsarean section and from symphyseotomy did not differ materially for the mother, but they did for the child, and the results for both mother and child were not so good for symphyseotomy as for Cæsarean section under equally favorable conditions. For this reason it seemed to him that there was no field for symphyseotomy as an elective operation before labor. The operation of symphyseotomy, however, did offer some advantages in the case of a woman who had been long in labor. Here the exhaustion of the mother added greatly to the danger of Cæsarean section.

Dr. G. L. Brodhead thought just as good cervical dilatation could be obtained from the use of the smaller bags as from the large and more clumsy ones. In the application of obstetric forceps he thought as much depended upon the operator as upon the particular style of forceps employed. He had seen wonderfully good results obtained with the common forceps, and very bad results with the axis-traction forceps. He did not believe in the rule of doing version whenever the head was movable above the brim, because the mortality was certainly less from slowly and carefully conducted forceps operations than from versions, and the danger to the child was less. Version was sometimes very useful in cases of flat pelvis. He was thoroughly in accord with what Dr. Cragin had said concerning symphyseotomy and Cæsarean section.

Santonin in doses of one grain every hour or two will usually give prompt relief in urethral irritation accompanying dribbling urine.—J. N. Tyfe.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 27, 1901:

	Cases.	Deaths.
Tuberculosis	287	204
Typhoid fever	20	7
Scarlet fever	669	44
Measles	330	9
Diphtheria and croup	290	58
Smallpox	56	8
Varicella	58	0
Cerebro-spinal meningitis	0	6

Instruments, no matter how carefully cleansed previously, are boiled for five minutes in a one-per-cent. solution of washing-soda, and are then placed in suitable vessels completely immersed in sterilized hot water, to which one-fourth part of five-per-cent. phenol solution may be added, and arranged on a table (preferably a glass one) at a convenient distance from the operating-table—the sponges, ligatures, sutures, and towels having been all carefully sterilized by some approved and reliable process.—Pearsons.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended April 26, 1901:

		Cases.	Deaths.
Smallpox—United States and Insular.			
Delaware, Newcastle	April 1st to 15th	4	
Florida, Jacksonville	April 13th to 20th	6	
Illinois, Chicago	April 13th to 20th	17	
Kentucky, Cynthiana	April 17th	6	
Lexington	April 13th to 20th	4	
Louisiana, New Orleans	April 13th to 20th	10	1
Minnesota, Winona	April 13th to 20th	2	
N. Hampshire, Manchester	April 13th to 20th	7	
New Jersey, Jersey City	April 14th to 21st	4	
Ohio, Cincinnati	April 12th to 19th	7	
Cleveland	April 13th to 20th	46	
Pennsylvania, Pittsburg	April 13th to 20th	1	
Steelton	April 13th to 20th	3	
Tennessee, Nashville	April 13th to 20th	1	
West Virginia, Wheeling	April 13th to 20th	1	
Philippines, Manila	March 2d to 9th	6	
Porto Rico, San Juan	April 6th	13	
Smallpox—Foreign.

THE TOXIC ORIGIN OF NEURASTHENIA AND MELANCHOLIA.[1]

BY M. ALLEN STARR, M.D., LL.D.,

NEW YORK,

PROFESSOR OF NERVOUS DISEASES, COLUMBIA UNIVERSITY.

WHILE the interest of the physician is commonly excited by rare and unusual cases rather than by the common run of disease, it is after all the ordinary light type of case which comes most frequently under his attention and demands his effort. There is no need to affirm the frequency of mild cases of neurasthenia and of melancholia, inasmuch as every practitioner sees such cases constantly. The complaints of a neurasthenic are so numerous and the general frame of mind of these patients is so depressing, that the disease fails to elicit very much interest on the part of the practitioner, or of the neurologist to whom in despair he often refers these cases. Yet it is my experience that a little care in their examination often enables one to classify them into a variety of different types, not only cerebral, spinal, and vasomotor types, but also into different classes according to the origin of the disease. Thus one can recognize clearly cases that are due to anxiety and worry; cases that are due to overexertion, mental and physical; cases that are due to beginning degeneration of the neurons, destined to go on to organic disease; and lastly, cases that are distinctly toxic in their origin. It is to the latter class that I wish to direct attention at the present time.

I do not wish to delay you by any long study of the symptomatology of this variety of neurasthenia. It usually occurs either in poorly nourished women, or in men about the age of forty-five who have lived rather freely, have taken little care of their diet and have indulged in the use of alcohol and tobacco, and who have neglected exercise.

The chief symptoms in this form of neurasthenia are headache, dull pressure in the head and back of the neck, sensations of fulness in the head with inability to concentrate the attention, irritability of temper, manifest irregularities of the circulation shown by cold extremities, and by frequent flushings and burnings in different parts of the body, and general disorders of the digestion, either of the nature of acid dyspepsia, or of considerable evolution of gas in the stomach and intestines, with irregular and very offensive stools. In these cases the urine is irregular in quantity, at times scanty, of high color and of high specific gravity; at other times profuse, light, and of low specific gravity, and at all times it contains large quantities of indican or indoxyl. In this condition a mild state of melancholia is very frequently associated with the neurasthenia, and in almost all cases of mild beginning melancholia the same symptoms are present.

The chief characteristic of this type is the alternation of feelings and symptoms at different times of the day. One can draw a curve representing the intensity of symptoms in these patients with remarkable accuracy, a depression in the curve representing the depression of spirits and intensity of suffering. From noon such a curve rises gradually toward the normal level. At 9 P.M. it begins to descend; during the night it falls to its lowest level, so that at 4 A.M. when these patients commonly awake, they are in the deepest distress of mind and are suffering the greatest discomfort of body. For a period of three or four hours the curve is then at its lowest point, but by breakfast time it begins to rise and continues to rise slowly until the normal level is almost reached at noon. This cycle of misery and well-being is so constant and so uniform that patients themselves readily recognize it. It is perfectly evident that a variable condition of this character must be produced by a varying intensity of cause, and the fact that the maximum of distress occurs in these patients after the sleep of the night, is an indication that it is not the wear and tear of exhaustion which produces their chief symptoms. It must be some toxic agent which accumulates in the blood during the period of sleep, which reaches the point of irritation early in the morning, which is counteracted by the activity of the day, and hence is less intense in its action toward afternoon. That this toxic agent is manufactured either in the intestines or in the stomach seems to be the most natural theory, inasmuch as activity in the digestive process appears to aid in the elimination of the poison. Exactly what this toxic agent is I do not know. As already stated, I find that indican or indoxyl is the one particular thing found in the urine in varying quantities, according to the general condition of these patients, and yet I do not suppose that indican is the active poison. It would be as foolish to affirm this as it would be to judge of the results of heat and power produced in a steam furnace by analyzing the character of the slag in the ash pan. Very much more exhaustive studies in the chemistry of digestion are necessary before we begin to approach any true knowledge of the active agents producing these effects.

But it is not necessary for us always to wait in medicine for scientific facts before attempting treatment. Some of the most valuable remedies that we have at our disposal are purely empirical in their origin. When a patient presents these evidences of toxæmia, he can be materially helped by a certain regimen and treatment, no one particular element of which is necessarily curative, but all of which combine to give relief.

First: Diet. This cannot be laid down in a uniform manner for all patients. The majority of them, I believe, do not digest milk well, and eggs as a rule do not agree with them, though occasionally raw eggs will be digested when cooked eggs will not. Meat of all kinds seems to me to agree very well with this type of patient, but meat soups are not well digested and therefore cream soups are preferable. Fish in all forms and oysters usually agree with such patients, and also certain types of vegetables; but potatoes, turnips, beets, and tomatoes are liable to give more trouble than other vegetables. Rice, macaroni, and hominy are usually well borne, but should not be cooked with cheese, and cheese as a rule is not well digested. Patients differ entirely from each other in their capability to assimi-

[1] Read at the meeting of the Association of American Physicians, Washington, May 1, 1901.

late breads and sweets, and it will not do to lay down any rule for the use of these articles; in fact in these cases various forms of diet and various articles of diet should be tried until the articles which disagree are ascertained.

Fluids: Tea almost uniformly disagrees with these patients, making them nervous and increasing their indigestion. In many of the patients, coffee acts as a desirable and pleasant stimulant, both in the morning for breakfast and after dinner, and does not in any way interfere with sleep. In others it acts as a poison and should be excluded. I believe that in all these cases alcohol should be avoided in every form, especially the sour wines and champagne. In about one-half of the cases whiskey can be taken without ill effects, but the stronger wines, like port and sherry, and all liqueurs are to be avoided. Occasionally a patient can take Rhine wine diluted, or the Austrian Vöslauer, without ill effects. Water should be taken very freely, and a good alkaline or lithia water is often of much benefit.

Drugs: The digestion must be aided in these patients by two classes of remedies: one which stimulates the liver to activity, the other which counteracts the evolution of toxic agents in the intestines. First, it is my habit to give these patients small doses of calomel (gr. $\frac{1}{10}$ every half hour till one grain is taken) every ten days and to give them a dose of podophyllin (gr. $\frac{1}{4}$) every ten days alternately with the calomel. It is also well to stimulate the liver by the use daily in the morning of either Carlsbad salt or a salt made by mixing gr. x. of salicylate of sodium with ʒ i. of phosphate of sodium and ʒ ss. of chloride of sodium. If this mixed salt is put in a large tumbler of sparkling water of any kind, and taken during the act of dressing in the morning, it will usually be beneficial. In this manner the liver is stimulated to action.

The second object—the counteracting of the toxic agent—is attained by one of three different remedies, and it is never possible to determine exactly which of these three in any one case will prove of service. The first is a combination of gr. v. of the sulphocarbolate of sodium with gr. i. of permanganate of potassium put up in a capsule which is coated with shellac so as to be insoluble in the stomach, and hence dissolve only in the intestine. Such capsules are given after each meal and on retiring. The second remedy that I use is a capsule of salol and castor oil—gr. v. of salol and ♏ x. of castor oil. This also is rendered insoluble in the stomach by a coating of shellac. The third remedy is given in the same manner, in capsule after eating, and consists of benzoate of sodium gr. ii., sulphocarbolate of zinc gr. i., and beta-naphthol gr. i. It is my experience that by the administraion of these remedies continuously for a considerable period a steady amelioration in the symptoms of intestinal indigestion will ensue, and, what is much more noticeable, an entire cessation in the periodicity of the alternations of the symptoms; the first evidence of relief being a quieter rest during the night, without any early awakening and a relief from the depression that occurs early in the morning.

Baths: The use of a hot bath on rising, at a temperature of 104° F. for three minutes, followed by cool sponging for one-quarter of a minute, is of importance, as nothing stimulates the general nutrition of the body better than such a measure, but in this type of patient the cold bath in the morning usually produces distress and is followed by a feeling of exhaustion, cold extremities, and discomfort.

Exercise and rest: In all cases an increased amount of exercise should be insisted upon, yet in many cases any long-continued exercise is most exhausting and is followed by a rapid action of the heart; hence it is far better for these patients to swing clubs briskly or to play a game of tennis for twenty minutes, thus getting into a pleasant perspiration, than it is to take an hour's horseback exercise or to play a game of golf which requires tramping two miles, though both of these measures occasionally can be endured and are beneficial. One very important element in the treatment is regularity in the amount of rest. These patients should be urged to lie down and relax all the muscles, the clothing being properly loosened, for one-half hour after each meal, and after any active exercise rest of the same duration should be enforced. One of the essential elements of successful treatment in these patients is a pleasant occupation for the mind, as their depression leads them to intensify their nervousness by introspection and self-observation. A variety of occupation should be sought and every means should be employed to keep them interested and diverted. An outdoor life is far better for them than a life indoors, and therefore if an occupation can be found which involves some activity in the open air it is desirable: the study of botany, the study of forestry, the running of a farm, the care of chickens, the occupation of an engineer or surveyor, the study of landscape gardening—all of these are pleasing occupations for men and women, and it is on this principle that travel and change of scene may be urged upon these patients. But whatever means are employed in their treatment, it seems to me that the essential element in their success is the counteracting of the toxic product within the body and the prevention of its formation.

POTAIN'S SIMPLE AND ACCURATE METHOD OF THE PERCUSSION OF THE HEART (WITH POST-MORTEM VERIFICATIONS).[1]

By GEORGE M. CONVERSE, M.D.,

NEW YORK.

While studying under the late Professor Potain in Paris several years ago, I learned to percuss the heart accurately and to keep records of the tracings obtained. Since then I have had ample opportunity to practise the method, and also to make post-mortem verifications of the same.

The exactness of result to be obtained by the technique of Potain is not generally known. For a proof of this statement open almost any book on physical diagnosis and turn to the subject of percussion of the heart. You will usually find the remark that, while the superficial dulness may be made out, it is not at present possible to obtain an accurate knowledge of the deep dulness or real size of the heart by percussion.

I purpose, therefore, to speak of it and to show by some verified tracings what precise and satisfactory results may be obtained.

It might be objected that this exactitude is not indispensable were it not for the fact that, in a goodly number of cases, the knowledge of the exact location of a murmur, with reference to the position occupied by the heart, furnishes a very important element of diagnosis; I refer to the considerable class of inorganic murmurs and to the errors of therapeutics ensuing from an incorrect diagnosis. The method of percussion is digital; the finger is to be preferred to Sansom's plexímeter, or any other plexímeter, because of its simplicity and because the finger gives a more intelligible measure of the resistance of the subjacent strata.

The percussion stroke must be moderate in force, precise, and single.

This seems elementary; in reality it is not. How many physicians use a single percussion stroke? Most

[1] Read before the section on medicine, New York Academy of Medicine, April 16, 1901.

men percuss twice, many three and four times, some six and more times on the same spot. In mapping out the heart, the single, clean stroke will enable one to judge of differences in pitch much better than the repeated stroke. By observing this rule, much pain may be spared the patient when percussing a painful liver, spleen, or tumor.

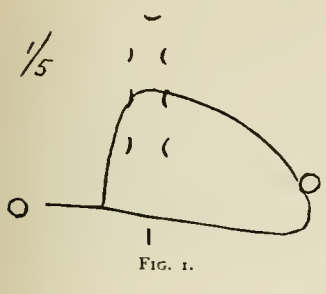

Fig. 1.

It ought to be moderate in force, because it takes but a moderate stroke to elicit a difference in pitch between a point lying over deep lung tissue, and another where the resonant layer is but 2 or 3 cm. in thickness.

The percussion must be concentric; that is to say, must proceed from points situated at a little distance from the heart, some 3 or 4 cm., toward its periphery. On reaching the border of the heart, covered as it is by lung tissue, there occurs a slight difference in the intensity of the sound, and, all important, a sudden rise in pitch. It is the instant recognition of this difference in pitch that is difficult, but it constitutes the key to the proper percussion of the heart. There the percussion stops, never proceeding over the organ,

Fig. 2.

where it is useless. Fig. 1 is an example of the tracing obtained on percussion of a normal heart.[1] This projection of the heart on the chest wall is mapped out by means of three lines and three angles.

The first line corresponds to the curved border of the left ventricle and forms the left boundary of the dulness. Normally it extends from the upper part of the sternal border of the second interspace to the fifth interspace, just within the mammary line. The second line forms the right border of the dulness, and corresponds to the right border of the right auricle and to part of the ascending aorta. Usually it merges in the right border of the sternum, from the second to the fourth interspace.

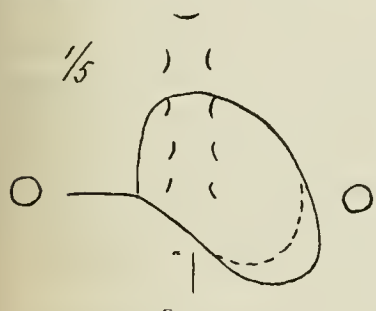

Fig. 3.

The third line should correspond to the curved border of the right ventricle, but as this border lies on and over the antero-superior surface of the liver, and as the two can but rarely be distinguished by digital percussion, a straight line is drawn from the upper border of the liver, at its point of junction with the right border, to the apex.

Of the three angles, the right inferior has already been determined, since it is formed by the junction of the right border with the line of the liver; the left inferior angle is rounded and corresponds to the apex. It may often be found by palpation, but always more surely by percussion; the superior angle, also rounded, corresponds to the point where the aorta leaves the immediate vicinity of the sternum to take its course backward toward the spinal column.

In practice several details must receive additional attention. The line of the liver must correspond, not

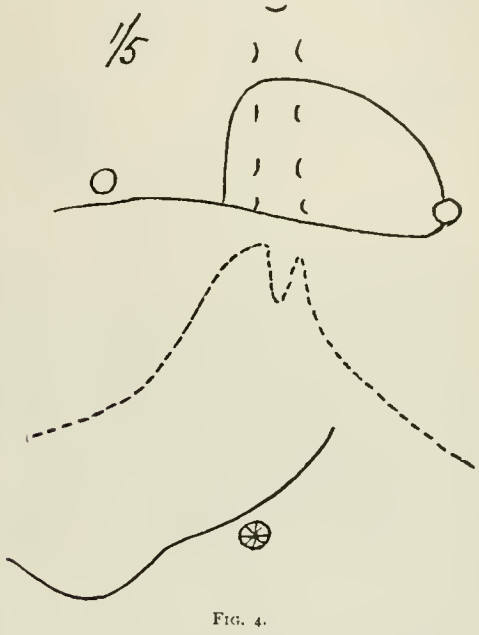

Fig. 4.

to the point where the liver comes in contact with the chest-wall, but to the upper part of its convex surface, which is situated behind a variable thickness of lung tissue. It is obtained by percussing from above downward along the right parasternal line, until a sudden rise in pitch is noticed, and not until flatness is reached.

That with this attention this line is not difficult to obtain is shown by the exactness of the post-mortem findings.

The apex is at times very difficult to locate. In two of the tracings it will be noticed that the apex, as found at the autopsy (dotted line), does not correspond exactly with the result obtained during life (continuous line). In one of these (Fig. 2), that of a woman forty-three years of age, who died of abscess of the liver, and who also had a mitral insufficiency, the apex had been made out by palpation as well as by percussion. Here, then, the difference was probably due to final retraction of the apex, as it was found that the heart had stopped in systole, and that the ventricles were empty.

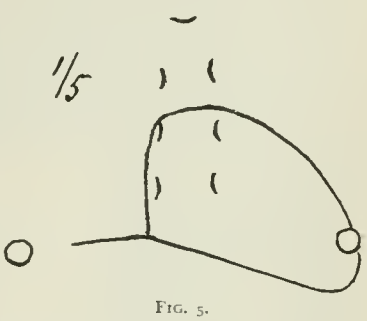

Fig. 5.

In the other case (Fig. 3), that of a man thirty-eight years of age, who died of carcinoma of the œsophagus, my notes do not state that the apex beat had been felt at the place marked on percussion; but as here also the heart had ceased beating in systole, it may be assumed that the difference was due to the same cause. With this exception, both tracings were exact.

The right border, as was said, usually merges in the right border of the sternum. The above tracing (Fig. 3) shows a marked exception, this border being found

[1] This tracing, as well as those that follow, has been reduced one-fifth.

at a distance of 3 cm. to the right of the sternum, and that with a perfectly normal heart.

Again, in the case of this man, aged forty-six (Fig. 4), who died of carcinoma of the liver, and whose

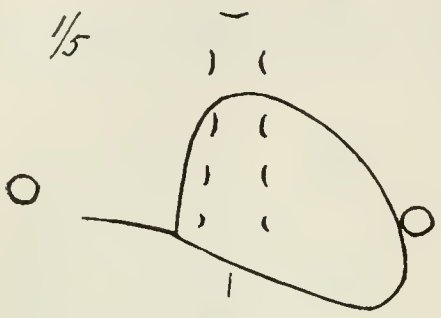

Fig. 6.

heart was normal, the right border was at a distance of 2 cm. from the sternum.

This tracing also shows to advantage the displacement of the lower sterno-costal cartilages on the right side, caused by the pressure of the enormous tumor.

In the two following tracings there is nothing particular to note. Both of these, like the others, were found to be perfectly correct. Tracing No. 5 is that of a man of forty who died of acute alcoholism and typhoid; the other (Fig. 6), that of a man of thirty-two who died of pneumonia. The heart was very pale and flabby.

The manner of taking these tracings for future reference is this: The results of the percussion having been marked on the patient's chest by means of a dermographic pencil, a few fixed points are now added; for example, suprasternal notch, intercostal spaces, and nipples; then a piece of transparent tissue-paper of appropriate size is laid on the chest, and these various markings, which are easily seen, are traced over it with the same soft pencil. The name, date, and such remarks as may be desired are added, and the tracing is complete.

When making a post-mortem verification of such a tracing, I placed it in position by means of the fixed points and then inserted long needles perpendicularly through the chest at five different points, namely, right inferior angle, middle of right border, upper part of left border, middle of the same, and lowest point of the apex. These remained in position during the removal of the sternal plate. The result, with the exception above noted, was always precise, the needles being found sometimes along the very edge of the auricle or ventricle; sometimes piercing the pericardium.

The tracings thus obtained and preserved in many cases give valuable indications for prognosis. Fig. 7 (dotted line) is the tracing of a man twenty-three years of age who came to the hospital for a second attack of acute articular rheumatism, and who, in addition to a slight aortic insufficiency, developed a dry pericarditis. When he left the hospital after a stay of two months, the heart had acquired the size shown by the outer continuous line, its development being observed and tracings made from time to time. Aside from other data available for prognosis, this increase in size, of which a good part was due to dilatation, showed the future disability of the heart to combat infection, or to adapt itself to the exigencies of any other but the most quiet sort of existence.

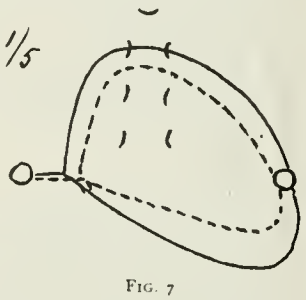

Fig. 7

In conclusion, the positive knowledge of the absolute size of the heart is of much value in the diagnosis and prognosis of disease, and especially of its own diseases.

This knowledge can be obtained by following a correct method. Potain's method is the most correct, since, on post-mortem examination, it gives an absolutely correct result.

The key to the percussion of the heart rests in the recognition of the differences of pitch of the percussion note and not with differences of intensity of the sound. The taking and preserving of tracings on a transparent paper is the simplest, quickest, and only accurate method of describing a heart for future reference.[1]

330 West Fifty-seventh Street.

THE TREATMENT OF PNEUMONIA, INCLUDING THE HYPODERMIC INJECTION OF SALINE SOLUTION.

By F. NEUHOFF, M.D.,
St. Louis, Mo.,
Attending Physician to St. Mary's Infirmary.

Dependent upon the objects we expect to accomplish by their administration, the remedies employed in the treatment of acute croupous pneumonia are conveniently divided into two groups, (1) specific, and (2) symptomatic.

(1) The remedies of the specific group are supposed to exercise a specific influence over the disease itself, either cutting it short or rendering its course less severe. To this group belong quinine, chloroform or creosote inhalations, the salicylates, and a host of other medicaments which have from time to time been brought forward by zealous therapeutists. Though for the most part the reasoning which prompted the application of these remedies appeared to be logical, and the tabulation of clinical reports which proved their efficacy was convincing, nevertheless, with the exception of their particular champions, no one seems able to obtain any noteworthy results from their use. From present indications, if we are to look for a future specific for pneumonia, our best hope would appear to be in the direction of serum therapy. Thus far, however, though bacteriologists have succeeded in immunizing animals against pneumococcus infection, they have not furnished us with any anti-pneumonic serum of any demonstrable curative value.

This being the sorry plight of our specifics for pneumonia, we must, as heretofore, place our sole reliance in the treatment of that dread disease on the second or symptomatic group of remedies.

(2) The group of symptomatic remedies has never had quite such alluring claims made for it as has the preceding group. The very fact that they are symptomatic precludes the application of these remedies from being routine. This renders their application more troublesome, requiring close observation and careful judgment of the symptoms of each particular case. On the other hand, this also renders the scheme of their employment capable of indefinite variation, improvement, and amplification.

It is the exploitation of a recently suggested and, as I hope to show, a useful adjunct to the symptomatic scheme of the treatment of pneumonia, that prompted the writing of this article. The names by which this adjunct has been variously designated are hypodermoclysis and saline infusion. It consists of the hypodermic injection, every six to twelve hours, of decinormal, *i.e.*, six-tenths of one-per-cent. common-salt solution,

[1] See Potain: "Clinique de la Charité." Musser: "Medical Diagnosis," 1900.

in quantities usually varying from one-half to one pint. No special apparatus is required. All that is needed can be found in every physician's office. Take the ordinary rubber syringe. Replace the hard-rubber tip of it by an antitoxin-syringe needle. Sterilize the whole apparatus by boiling it, or by pumping boiling water through it. Now put ninety-two grains of pure table salt into one quart of clean water, and boil this solution. Let it cool off to about 100° F. Next put the prepared syringe into the solution. Work the bulb of the syringe until the salt solution issues in a steady stream from the needle. Now insert the needle deep under the breast of the patient and again work the bulb slowly until you have infused the desired amount of the solution. The site of the injection must of course have been previously sterilized. The injection is not painful, and when aseptically done is devoid of unpleasant sequelæ.

To illustrate the place which the saline infusion should occupy in relation to the other treatment of pneumonia, I will give a *résumé* of the clinical features of eleven consecutive cases of pneumonia admitted to the medical ward under my charge. These eleven cases include all the cases that were admitted to my ward in the space of thirty days in the midst of the so-called pneumonia season. These cases were on an average of such a degree of severity as are usually to be seen in a hospital ward. The ages of the patients ranged from twenty-one to seventy. The previous health of most of them had been good. Their habits had, as a rule, not been of the best. Many of them were alcoholics, and all used alcoholic liquors to some extent. The care which they had received during their illness prior to their admission had always been very bad. In order to reach the hospital many of them had to travel a considerable distance (one of them eighty miles) at a critical period of their disease.

The plan of treatment of these eleven cases after they reached the hospital was as follows: (1) The application of dietetic and hygienic measures. (2) When required by pain or great restlessness, morphine or heroin was given in necessary doses. (3) When the temperature was high, cold sponging was used; when this did not control the temperature and the latter became very high, small doses (gr. iiss.) of phenacetin were occasionally given. (4) When the pulse began to show signs of failing, strychnine, whiskey, tincture of strophanthus, one or all, were administered, as the condition of the pulse from time to time seemed to indicate. When collapse threatened, or when, in spite of the stimulants above enumerated, the pulse weakened, then we injected hypodermically every twelve to six hours one-half to one pint of the decinormal saline solution. Moreover, camphor and olive oil (1 : 10) were hypodermically administered, ℥ xxx. every twelve or six hours, when the condition of the pulse became very alarming. Oxygen inhalations were not employed, as no appointments for this purpose were at hand. Digitalis was not used at all, as my previous experience with this drug in pneumonia had been disastrous.

Of the eleven cases three were deemed to demand and be suitable for the saline infusion as an adjunct to the other treatment. At the time when I began the infusion treatment in them the condition of these patients was such as in my previous experience had usually terminated fatally. Of the three cases one was fatal, although even in this the saline infusion each time produced temporary improvement.

Besides the one fatal case of these three, one of the other eight patients also died. His death, however, was due to a complicating purulent meningitis, confirmed by autopsy. He was never given hypodermoclysis, as he presented no indications for it. He had passed the crisis of the pneumonia, and for two days his pulse, temperature, and respiration were almost normal, when suddenly symptoms of meningitis supervened. The patient soon became comatose, and the coma rapidly deepened until a fatal termination occurred. The pulse remained bounding up to twelve hours before death.

Of the others in whom the saline was not used, it is unnecessary to give separate clinical histories. They were by no means light cases. Many were delirious. In the majority the temperature touched 104° or 105° F., the respiration 40 to 56, and the pulse 120. The pulse, however, either retained its strength and rhythm or was amenable to the cardiac stimulants enumerated in the plan of treatment outlined above. A few of the patients near the crisis of their illness took ℥ xviii. of whiskey in twenty-four hours, besides gr. $\frac{1}{30}$ of strychnine every three or four hours and ℥ x. of tincture of strophanthus every six hours. Some of them, on the other hand, passed the crisis without taking any medicine except anodynes as needed. When I say medicine, I include all alcoholic drinks in that category.

I give below the clinical histories in detail of those cases in which hypodermoclysis was used:

Case I.—H. M——, single, laborer, aged forty-two years, born in Ireland. The patient became sick February 4, 1901, and was admitted to the hospital February 7th. He was a strong, well-nourished man, and had been a moderate indulger in alcoholic liquors. His present illness began with a chill, fever, pain near the left nipple, and a short, dry cough. When he was admitted his cough was very painful and accompanied by a viscid, rusty-colored sputum, showing pneumococci in pure culture. Temperature, 104.6° F.; pulse, 120, rather weak; respiration, 36. The left lung was consolidated along its whole posterior aspect. The patient's cheeks had a dusky red color. His skin was very hot and dry. During the next three days the symptoms became aggravated. The temperature reached 105.2°, the respiration 56, and the pulse 124. Delirium, at first intermittent, became constant. The treatment thus far had consisted of gr. $\frac{1}{8}$ morphine when the pain was severe, gr. $\frac{1}{30}$ strychnine every four hours, cold spongings, and two doses of phenacetin, gr. iiss. each.

During the following two days the patient's general condition became worse. Though the temperature declined to 102.8°, the respiration still remained 56, and the pulse 126, weak and irregular. Whiskey and tincture of strophanthus had been added to the treatment.

Finally, at 5 P.M., February 12th, the patient's condition was very critical. Temperature, 101.8°; pulse, 150, very weak and intermittent. The tongue and the whole inside of the mouth were parched. I now gave the patient one pint of decinormal saline solution hypodermically. While the saline was being slowly injected, I soon noticed an increased volume of the pulse. An hour afterward the tongue and skin became moist. The patient undoubtedly looked brighter and his intellect was a little clearer. Two hours before the saline was administered, the nurse in my absence had noticed a failing of the pulse and had given ℥ xxv. of a 1 : 10 camphor-and-olive-oil solution, kept on hand for such emergencies. On the morning following the evening on which the saline infusion had been given, the temperature had fallen to 99.8°; respiration, 48, and pulse, 100, weak and intermittent. By this time the strengthening effect of the infusion seemed to have again worn off. Another pint of the saline solution was therefore injected, and again the pulse improved. I now ordered the patient to have one pint of the saline solution every twelve hours. All this time the heart stimulants previously ordered were continued. The camphor and oil were also injected on one other occasion.

On February 16th, the twelfth day of the disease,

the pulse retained a fair strength and the infusion treatment was suspended. On this day the temperature was 98.4°, and the respiration 36. The heart tonics were gradually reduced, and finally stopped. From now on convalescence was uneventful, except that at the site of the camphor injections abscesses appeared, the thick gelatinous pus from which was sterile. The saline injections produced no unpleasant local phenomena.

Case IV.—W. C——, single, laborer, aged forty-five years, born in Indiana. His habits were alcoholic; his previous health was good. The patient was admitted February 16, 1901. He had been sick two weeks with general malaise, fever, and cough, accompanied by the expectoration of mucus. This kept him in bed part of the time. Two days before admission to the hospital he suddenly grew very much worse, developing a very distressing cough with rusty-colored sputum. These symptoms had increased in severity. The patient, on admission, was very nervous and restless. His face and tongue were fiery red. Though rational when awake, he talked constantly in his sleep. The left lung gave dulness, bronchial breathing, and increased vocal resonance over the upper part posteriorly, and in the upper axillary region. There were subcrepitant râles all over the uninvolved portion of the left lung and all over the right lung. Friction sounds could be heard in the left axilla. The temperature in the evening was 104°; pulse, 100; respiration, 32. The sputum showed pneumococci. Diagnosis: Acute croupous pneumonia supervening on a general bronchitis. The treatment thus far consisted of gr. $\frac{1}{8}$ morphine every four hours. February 17th, temperature, 104.8°; pulse, 122; respiration, 38. There was a constant talkative delirium. I now added gr. $\frac{1}{30}$ strychnine every four hours to the medication, and ordered cold spongings, which seemed very grateful.

February 18th. Temperature, 103.4°; pulse, 110; respiration, 38. Whiskey and strophanthus were added to the treatment.

February 19th. The patient's general condition was worse. His cough was very harassing. He was moving his hands about in an aimless manner continually. He chattered incessantly in his delirium. The temperature in the evening was 104.4°; pulse, 120; respiration, 38. No change was made in the treatment except stopping the morphine and increasing the whiskey to ℥ xviii. a day.

February 20th. All symptom were about as yesterday, except that the pulse was evidently getting weaker in spite of all stimulation thus far employed. It beat 140 per minute. Respiration, 38. I now instituted the saline hypodermic treatment, giving one pint every twelve hours. Each infusion strengthened the pulse and lessened somewhat the intensity of the delirium and the restlessness. After the institution of the saline treatment the pulse never went above 126. The temperature fluctuated around 103°. The respiration remained 38.

February 23d. A change for the better was apparent. Pulse, 100; temperature, 99°; respiration, 32. The delirium had disappeared. The saline infusions were now no longer required, and the other heart stimulants were gradually cut off. The patient made a rather slow, though complete recovery.

Case X.—J. O——, sexton, single, aged fifty-eight years, born in Ireland, was admitted to the hospital March 5th. He was emaciated and looked as if he might have been in ill health for some time, though he denied this. His habits had been good, and he never drank alcoholic liquors to excess. He became sick two days ago, and being unable to receive any attention in his boarding-house, he came to the hospital, though to get there, he was compelled to ride seven miles over rough roads on an exceedingly raw and chilly afternoon. When admitted, he was completely chilled through. He looked blue. His feet, hands, and the tip of his nose felt like ice. His pulse was scarcely perceptible, feeble, intermittent, 118 per minute at the wrist. Some of the beats probably did not reach the wrist, being too feeble. Rectal temperature, 102.5°; respiration, 40. Cough occurred in severe paroxysms. The sputum was very viscid, orange yellow in color. The whole right lung in front as well as behind gave physical signs of hepatization. There were, moreover, coarse subcrepitant râles heard over both lungs. I immediately ordered all customary stimulants—strychnine, strophanthus, and whiskey; heat was applied to the lower extremities, but all seemed to no purpose. The patient would not rally.

March 6th. The patient was still worse. Temperature, 103°; pulse, too weak to be counted; respiration, 40. Delirium was present at times. Prune-juice expectoration was noted. The tongue was dry, the skin hot and dry. I then ordered camphor and oil in ♏ xxv. doses hypodermically every six hours. Also a saline infusion of one pint was given. After this the pulse became a little stronger, but the effect seemed to be very evanescent. I therefore repeated the saline infusion every six hours, giving ℥ viii. at a dose. The camphor was also repeated every six hours, being given in the intervals between the infusions.

March 8th. Temperature, 103.4°; pulse, 150, irregular; respiration, 60. Each breath was accompanied by an audible rattling in the trachea. The patient was partly unconscious.

March 9th, 4 A.M., death ensued.

While in this case the saline infusion did not avert the fatal issue, it had a well-marked though evanescent strengthening effect on the pulse. It no doubt prolonged life somewhat, and thus gave additional time in which a favorable crisis might have occurred had the case been not quite so unfavorable.

I draw the following conclusions as to the status of the saline-infusion treatment in acute croupous pneumonia:

It is a useful adjunct to other treatment in selected cases.

It acts as a powerful heart stimulant when other heart remedies can no longer sustain the flagging circulation.

It increases the secretions, and moistens the tongue and throat as well as the skin. It lessens the delirium. Other observers have noticed that it also improves the respiration, but of this I could not convince myself.

It is contraindicated in pulmonary œdema.

Some pneumonia patients apparently die of collateral pulmonary œdema not consequent on a failing heart. In these cases saline infusions are not applicable. Other pneumonia patients apparently die from heart failure, or a pulmonary œdema caused by heart failure. In this latter class of cases the saline infusion averts the tendency to death by sustaining the heart when nothing else can, and thus it gives additional time for a favorable turn to occur in the disease.

On a Form of Chorea Met with during the Course of Erysipelas.—Fornaca Luigi reports the case of a girl of fourteen years suffering from facial erysipelas. On the third day of the disease choreic movements of hands, feet, and face appeared. Spinal fluid was withdrawn by lumbar puncture, and the presence of the streptococcus was demonstrated. The patient recovered perfectly from both erysipelas and chorea. The streptococcus has been found in other cases of chorea, and further researches in this direction would be of value.—*La Riforma Medica*, April 1, 1901.

SYPHILIS IN THE WELL-TO-DO.

By J. A. McDONALD, M.D.,

NEW HAVEN, CONN.,

INSTRUCTOR IN DERMATOLOGY, YALE UNIVERSITY.

When the victorious troops of Charles VIII. spread syphilis all over the southern part of Europe, there began an epidemic which was frightful, not only on account of the numbers afflicted, but because of the disastrously destructive character of the disease. History records that a monarch of France died of syphilis, and, if popular opinion may be trusted, royal families of the present day are not exempt from its taint.

Nobleman or common soldier, the picture in the sixteenth century was the same. Faces were mutilated by the destruction of the nose, the nervous system was shattered, the skin was covered with loathsome sores. From this picture, and from the frightful traditions which have been handed down to us by our panic-stricken predecessors, I submit that we have derived an altogether erroneous idea of the nature of the disease as it occurs in our own day and generation.

Many of us have had difficulty, as has the writer, in getting away from the conception, formed during our undergraduate life from some miserable old hospital case, which went on from bad to worse in spite of treatment, finally to pass into the grave uncured.

That the disease is a most formidable one, potentially destructive as it is to almost every organ in the body, is a fact readily admitted by all. The neurologists, basing their statistics very largely on hospital cases, point at it as the cause of some of the most hopeless forms of paralysis. The madhouses of the land are recruited annually with no inconsiderable number of its victims. The surgeons of every hospital are no strangers to its destructive power. Dermatologists recognize and are powerless to remove the tell-tale scars produced by its ravages. The very name of syphilis produces consternation in the breast of its victim, and many a suicide has resulted from dread of the consequences of the disease.

For some years the writer held a most melancholy view of syphilis, wheresoever and in whomsoever it might occur. But gradually there has crept in, first the suspicion, later the belief, and now the conviction, that the disease, when it occurs in private practice, is not only, in the average case, a mild affection, but that it subjects its victims to less pain, mutilation, and loss of time than many a trivial complaint.

To show that this opinion is justifiable there is adduced an analysis of one hundred and fifty consecutive cases of syphilis occurring in the private practice of the writer, and almost exclusively belonging to the well-to-do classes. Of the one hundred and fifty, eighty-nine were in males and sixty-one in females. The ages ranged from five weeks to seventy-nine years. There were five cases of hereditary syphilis, of which two patients died from the disease.

The one hundred and forty-five adults with acquired syphilis were divided into the following classes:

First. Those having mild, transitory lesions which left no trace when they disappeared. These included pharyngitis, inconspicuous loss of hair, macular and papular eruptions, or mucous patches. Some had several of these lesions, others only one or two. To this class sixty-five per cent. of all the cases belonged.

Second. Those showing destructive lesions of any sort whatever, from the pustular eruption which left scars, to the necrosis of bones. This class included twenty-six per cent. of the cases.

Third. Those cases which exhibited considerable severity for a time, but which finally cleared up completely, leaving no trace. This class included cases in which the hair fell out very conspicuously, in which laryngitis was troublesome, and in which there were transitory internal complications believed to be syphilitic. This class numbered six per cent. of the cases.

Now let us examine a little more closely the make-up of class two—the destructive class. This made up twenty-six per cent. of all the cases. There were twenty-seven cases of ulcerating cutaneous and subcutaneous gummata, three destructive bone lesions, one phagedenic chancre, three pustular syphilides resulting in scars like pock-marks, one permanent case of ulceration involving the vocal cords, and four cases resulting in loss of substance of the tongue—gummata, to be accurate.

Twenty per cent. of all the cases, therefore, showed destruction of tissue of one particular type, from the breaking down of cutaneous, subcutaneous, or lingual gummata. Now if there is one form of destructive ulceration which is more amenable to treatment than another, which is less painful and more readily healed, that form is ulceration from the broken-down gummata of syphilis. As a matter of fact, most of such patients in the preceding collection were readily cured. There were only four cases altogether which were severe enough to cause the patient temporarily to give up his usual occupation, and in no single instance was the individual confined to his bed by the disease. Six per cent. of the destructive cases are left for comment. Of these, three cases involved loss of bone substance, requiring surgical treatment to arrest the disease. One case resulted in a permanent impairment of the voice.

We may summarize, then, by saying that in the series of one hundred and fifty cases of syphilis there were three per cent. of hereditary cases, and ninety-seven per cent. of acquired. The mortality of hereditary syphilis was forty per cent. Of the acquired cases, sixty-five per cent. had from beginning to end nothing but mild, trivial, transitory lesions, which left no trace when they disappeared. Six per cent. suffered pretty severely from laryngitis, alopecia, and the like, but recovered completely, without perceptible impairment of any organ. Twenty per cent. suffered from gummata, which left scars, but which were readily amenable to treatment, and healed up satisfactorily. Six per cent. only were in any sense formidable, and not a single case was by any means appalling.

Now is this a disease to be especially alarmed about? If the above statistics represent average cases, certainly not. But do they represent average cases? As has been said, the list is made up almost entirely of well-to-do people. They applied for treatment, not to a general practitioner, but to one who confines his practice to skin and venereal diseases. Therefore, nerve lesions were not found in a single instance. The brain, spinal cord, and arteries were not mentioned in what precedes. The neurologists will very likely assert that these identical cases will later exhibit central lesions. But this is probably not so. For many of the cases cited were not instances of freshly acquired syphilis, but chronic cases, in which many years had elapsed since the disease began, and in which nerve lesions had abundant opportunity to appear. And that the cases which were treated for two years, as most of them were, by the intermittent administration of mercury in the largest tolerated doses, will not later suffer relapse, we have the authority of the most eminent syphilographers for believing.

That the difference between the syphilis of the well-to-do people and that of the poorer classes might be clearly shown, one hundred and fifty consecutive cases occurring in the dermatological clinic of the New Haven Free Dispensary during about the same period

were tabulated according to the scheme above, with the following results:

Of one hundred and fifty cases ten were hereditary and one hundred and forty acquired. Of the acquired cases, the mild, transitory lesions, like macular and papular syphilides, mucous patches and mild alopecia, made up thirty-three per cent., as contrasted with sixty-five per cent. in private practice. Of the destructive lesions there were fifty-one per cent., compared with twenty-eight per cent. in the foregoing series. Of bad cases not included in the two preceding classes, there were two of extensive syphilitic paralysis, two of iritis, three of onychia, and three of severe periostitis.

When it is remembered that many of these dispensary cases were seen but a few times, and that only a small proportion of them underwent a truly thorough course of treatment, it will have to be conceded that, in all probability, it is from this class, and not from the other, that the distressing hospital cases, the paralytics and the insane, are mostly recruited.

Syphilis in the well-to-do, then, is a totally different disease from syphilis in the poor. What makes the difference? Crops and diseases are alike, in that both flourish best when the seeds from which they spring are themselves the product of active growth, when the soil is favorable for their culture, and when the external conditions are propitious. Now is it the seed, the soil, or the environment which makes the difference in the syphilis of the rich and the poor? No obscure or far-fetched theory need be invoked. I opine that all three elements are involved.

In certain years epidemics of scarlet fever have been characterized by exceeding mildness. In other years the fatality has been alarming. Rich children and poor conform (generally speaking) to the type of the cases from which they themselves have contracted the disease. The common source of supply is most often the public school. But syphilis is contracted in no such way. The poor man contracts syphilis from an equally poor woman. The chances are that she has been only meagrely treated. The disease is therefore more severe.

The rich man, on the average, is more choice in his amours. Cleanliness, wholesomeness, and neatness appeal to him. Therefore the fashionable prostitute takes care of herself—her health and her person—or she knows she will sink even in her own social scale. In other words, her syphilis is better treated and therefore less severe. Of course we all know that malignant syphilis may spring from mild cases, but this is not the rule. So much for the source of supply.

The soil is also different. Not every man of means is the scion of a robust stock. But the very qualities which have made his ancestors able in the race of life to outstrip their competitors and gather in the prizes are handed down to him, though, forsooth, in many instances greatly diluted. The soil, indeed, is probably the least potent factor in determining the type of the disease. Other things being equal, the brawny laborer should make a better fight against the disease than the less rugged banker. But other things are not equal. The poor man cannot take the same care of his health as the rich man, and in this particular is decidedly handicapped in fighting the disease in question. He must often work beyond his strength, breathe impure air, expose himself to inclement weather, and eat unwholesome food. He cannot afford to have medical attendance, even the free clinic necessitating his absence from work. Acquaintance with the privations of poverty makes him callous to his own condition, and, in a word, he neglects his treatment.

Optimism, then, not pessimism, concerning syphilis as it occurs in private practice, is the keynote of this paper. But no physician who is called upon to treat this disease should fail to make it perfectly plain to his patient that a failure to submit to a thorough course of treatment for the full period of two years will, in all probability, result in disaster.

1142 Chapel Street.

SUBARACHNOID SPINAL COCAINIZATION AS A MEANS OF INDUCING SURGICAL ANÆSTHESIA.[1]

By EDWARD N. LIELL, M.D.,

JACKSONVILLE, FLA.

FORMERLY LECTURER ON GYNÆCOLOGY, NEW YORK POLYCLINIC.

As chairman of your section on gynæcology and obstetrics, I shall endeavor to merit your approbation and enlist your interest in presenting to you the results of my personal work and also my observations in a field of surgical anæsthesia new to all of us.

A recent advance in surgery is the method of inducing anæsthesia by injection of a solution of cocaine into the subarachnoid space of the lower portion of the spinal canal. By this procedure complete insensibility to pain usually results from the umbilicus, and even from the axilla, to the toes, causing the sharpest steel to lose its sting and robbing pain of victory, while patients retain their full mental faculties.

The innovation is almost revolutionary in technique. It is within a generation that surgery has made a radical and triumphant departure from former methods through asepsis. Here, because of the latter, we have a production which is brilliant! It excites admiration and impresses one; and this because of its apparent simplicity as much as because of the results attained. Operations upon the lower extremities, the genito-urinary tract, the abdominal and pelvic organs, the kidneys and bladder, all seem specially well adapted to this procedure.

True anæsthesia is not produced, but complete analgesia only, lasting for a sufficient length of time to admit of the performance of any operation below the regions stated. In this connection, an editorial in the *Medical News*, October 13th, humorously referred to a vivid imagination conceiving of the analogues of the engravings of the old Vesalian and Albinian anatomies, in which delicate ladies daintily held up the lacework of their own omenta for the inspection of the beholder, in the possible illustrations of the surgeries of the future, which might portray the interested patient as assisting the surgeon by holding a retractor or clamping his own arteries. Yet from personal observation in the numerous instances observed at the New York Polyclinic and the Post-Graduate hospitals, in October last, as also at the Methodist Episcopal Hospital in Brooklyn, I can assert, and could readily demonstrate, that this humorous picture is but little overdrawn.

The essentials of technique include a thorough asepsis. The needle and syringe should be thoroughly sterilized and the skin over the local area of injection thoroughly cleansed, as also the hands of the operator. To avoid the introduction of any possible infection in the spinal canal by puncturing the skin with the needle, I make a small incision through the skin first with the point of a scalpel, after anæsthetization of the area of puncture by subcutaneous cocainization. I use a gold needle of fine calibre, from three to three and a half inches in length, having a short bevelled point, in order to avoid penetrating the membranes too far. The piston or barrel of the syringe is graduated to thirty minims or more.

Regarding the preparation and sterilization of the cocaine solution, I prefer that of Dr. George B. Fowler, of

[1] Read at the twenty-eighth annual meeting of the Florida Medical Association, held at Jacksonville, April 10 and 11, 1901.

Brooklyn, using sterilized water and boiling about one minute; to boil it a longer time renders it liable to become inactive and thus unreliable. Yet by whatever manner of means the cocaine solution may be made, failures in anæsthesia will occasionally be met with.

In the introduction of the needle the position to be assumed by the patient is important. Seated on a table, the body should be inclined slightly forward, the distance between the vertebræ being thus somewhat increased, the needle entering more readily.

The point of puncture is one of election as to interspinous space, the second, third, or fourth space commending itself, although there seems to be a predilection for the third and fourth. As a guide to the seat of puncture, a point midway between the spinous processes and about one-half inch to the right or left of the median line can be taken; or a horizontal line drawn, connecting the iliac crests, crosses the lower border of the fourth lumbar vertebra. I introduce the needle at a slight angle from below upward and without inward, because of the position of the spinous processes. Gently but firmly pressed in, the escape of the cerebro-spinal fluid, drop by drop, marks its entrance into the subarachnoid space or spinal canal. The finger being placed over the needle opening, the syringe containing the requisite quantity of cocaine solution is then attached and the contents are slowly injected, about two minutes being taken to complete the injection. I then withdraw the needle and close the point of puncture with collodion. Anæsthesia, or rather analgesia, is present usually within ten minutes. When complete, it is sufficiently prolonged to accomplish the operator's purpose. If no evidence be present after a wait of fifteen minutes, a second injection can be given. Some patients are readily influenced by small doses, others require considerably more, the hyperæsthetic and nervous person being a type of the latter. Anæsthesia is often absolute, leaving nothing to be desired; yet the fact is equally certain that, despite a thorough technique, there have been many disappointments, either partial anæsthesia or absolute failure necessitating a resort to general anæsthesia. The area of anæsthesia varies considerably, being from the umbilicus down in some cases, while in others it reaches as high as the breasts, and even to the collarbone in rare cases, an instance of which I saw personally.

From our present knowledge, we may glean failures to be the result of:

1. Inert cocaine solution, the result of prolonged boiling or repeated sterilization.

2. Idiosyncrasy to the drug, with which may or may not be associated intensely neurotic temperaments.

3. Faulty technique—too short needle, imperfect syringe, non-entrance of needle or fluid into the spinal canal.

4. Too small a quantity of drug employed.

The disagreeable features of the post-operative symptoms usually associated with this procedure—not necessarily due to the drug, since several of these have appeared when puncture was made and a small quantity of cerebro-spinal fluid withdrawn, and before any injection was given—are:

1. Nausea and vomiting, the latter being rather projectile in character, of short duration usually in the majority of cases.

2. Headache, at times intense, is of frequent occurrence; its severity and duration are variable.

3. Increased temperature in almost every instance, not infrequently as high as 103°, disappearing within twenty-four to thirty-six hours.

4. Increase in pulse rate, appearing shortly after anæsthesia is present.

5. Added to these may appear vertigo, pallor, coldness of surface, and prostration. Abstinence from food for several hours previous to the injection tends to minimize attacks of vomiting. To counteract any seeming dangers from this method, the preliminary use of strychnine may be made hypodermically, or of whiskey by the mouth. For the intense headache, gr. $\frac{1}{150}$ hyoscine hydrobromate has acted favorably, while to lessen post-operative nervous shock gr. $\frac{1}{100}$ nitroglycerin has been given with good result. Symptoms of cocaine toxicity are thought to be due to spinal shock or to a disturbance of the equilibrium in the spinal canal, as a result of the sudden increase of pressure in the subarachnoid space; to too rapid diffusion toward the brain, or to the quantity of cocaine injected.

When ether and chloroform are objectionable or are contraindicated, as in cardiac disease, nephritis, bronchial and pulmonary conditions, this method of inducing anæsthesia has its legitimate field in exploratory and necessary operations below the diaphragm.

In a paper read by Dr. Goldan before the New York State Medical Association, in October last, which meeting I attended, he gave a history of twenty-seven cases in which the method has been used by him, with two failures, his first two cases. The only absolute failure I personally noted was one at the Post-Graduate Hospital, in the gynæcological clinic of Professor Boldt. Twenty minims of a freshly prepared two-per-cent. solution of cocaine hydrochlorate were injected by Dr. Goldan. There being no analgesia after a wait of twenty minutes, a second injection of ♏ xv. was given. At the end of three-quarters of an hour the method was in this case declared an absolute failure, and it became necessary to resort to a general anæsthetic. The technique throughout was perfect, and no cause could be ascribed for such failure.

A rare and instructive case was one in the clinic of Dr. Chetwood, at the New York Polyclinic, it being one for suprapubic cystotomy and perineal section. Twenty minims of a two-per-cent. solution of cocaine were injected by Dr. Goldan between the fourth and fifth lumbar vertebræ, followed in twenty minutes by ♏ x. more, between the third and fourth vertebræ, without any analgesia. Through the interest taken by Dr. Chetwood in the method, with the acquiescence of the patient, the operations were postponed, a second trial being given four days later, this time with complete success after but one injection of ♏ xx. Both operations were performed at one sitting, the anæsthesia lasting fully one and one-half hours. No explanation could be given as to the cause of failure one day and its complete success several days thereafter, the conditions being apparently the same each time.

I desire here to record two cases in which I have made use of subarachnoid cocainization. The first was one in which I performed curettage of the uterus, injecting ♏ xx. of a two-per-cent. solution of cocaine hydrochlorate. Anæsthesia was complete in twelve minutes, being of one hour and ten minutes' duration. There was complete absence of discomfort or pain.

Upon the second patient I performed three operations—curettage, trachelorrhaphy, and perineorrhaphy, all at one sitting. Anæsthesia was complete in this case also from a ♏ xx. injection of a two-per-cent. solution, and lasted fully one and one-half hours. Vomiting and headache were present in both instances, but not to a decided degree. In each case there was an increase in the pulse rate and temperature, the former rising in the second patient to 116 and the temperature to 100.5°, but falling to normal within twenty-four hours.

Dr. Marx, in recording one hundred and twenty-five spinal punctures, labor and operative cases included, states that he had two absolute failures occur in succession, both in intensely neurotic women. By repeated injections, he has carried through a labor case

lasting eight hours, with practically no pain. In his opinion, the injection is best indicated in multiparæ when the os is more than half dilated; in a primipara, when it is fully dilated.

Prof. Geo. R. Fowler, of the New York Polyclinic, recently recorded his experience with spinal anæsthesia, embracing eighty-one cases, with five failures. He classified them as follows: Twenty-six operations involving the peritoneum, thirty-four operations in the pelvic region not involving the peritoneum, five amputations, thirteen operations upon the lower extremities, three operations unclassified. From the results obtained, he concludes that the extent of the analgesia, as well as its duration, depends in a measure upon the amount of the cerebro-spinal fluid present; that progressive dilution of the cocaine solution, from the point of introduction, lessened the effect of the drug upon the nerve structures with which it came in contact, until finally, if the amount of cerebro-spinal fluid be much larger, the effect was practically nil at points high up in the canal. In a series of twenty-one cases reported by Drs. Hawley and Taussig, of St. Louis, they observed the fact that the duration of anæsthesia was dependent, as a rule, on the quantity of cocaine injected; gr. $\frac{1}{5}$ causing anæsthesia on an average for one hour and twenty-one minutes; gr. $\frac{1}{4}$ for one hour and twenty-six minutes; gr. $\frac{1}{3}$ for one hour and fifty-nine minutes. Cocaine, when pasteurized, gave an average of one hour and fifty minutes' duration, while boiling gave but thirty-five minutes. Dr. J. B. Murphy, of Chicago, at the recent meeting of the Western Surgical and Gynæcological Association, stated he had been able to collect five hundred and ninety-two cases of subarachnoid cocaine injection, of which number twenty-five were complete failures, and but four partial failures, with one death attributable to the drug, in Tuffier's clinic.

Dr. Robert F. Weir states that, out of three hundred and sixty-two cases collected by him, rather alarming symptoms occurred in about one in thirty. Of those who were frank enough to record complete failures, he mentions Fowler, five in eighty-one cases; Goldan, three in thirty-one; Marx, two in one hundred and twenty-five; Murphy, one in twenty-five. In this connection I might state that, like ether, chloroform, and nitrous oxide, in many instances there were absolutely no immediate sequelæ attending.

The cases recorded by various operators were usually unselected, the ages ranging from two and one-half to sixty-nine years. Renal, cardiac, and pulmonary lesions were in many instances disregarded in order to give the method an absolutely fair trial. Yet but one death is recorded. As compared with ether and chloroform, this is by no means a bad record when we stop to consider that the method is still in its infancy. Face to face with its importance in surgery, gynæcology, and obstetrics, it should, however, by no means be approached in anything but a serious manner. The ever-present danger of meningitis, through a faulty aseptic technique, is not to be lightly considered.

From the foregoing, it can be seen that the injection of cocaine into the subarachnoid space in the lumbar portion of the spinal canal, for the production of analgesia and anæsthesia below the point of application, has passed the experimental stage. We are justified in entertaining the hope that this method will have its field of practical usefulness in the near future along with ether, chloroform, and nitrous oxide. It not only dispenses with the services of the assistant, but complicating inhalation or aspiration and hypostatic pneumonias are averted.

Specific for Dysentery.—In its acute form sulphate of magnesium, properly administered, acts as a specific. —CRUIKSHANK.

Clinical Department.

KELOID FORMED UPON A VACCINATION SCAR.

BY FREDERIC GRIFFITH, M.D.,
NEW YORK,
SURGEON, BELLEVUE DISPENSARY.

AN observer in an Indian medical journal reports from Hong-Kong two cases of keloid after vaccination in women, presumably English. Glycerin virus was used and in each instance "took."

The history of a case of my own was as follows:

M——, female, white, aged nine years, had been vaccinated, under compulsion, by one of the medical school inspectors five months before I saw her. The scar following had been displaced by a keloid of marked similarity in size and shape to a large lima bean. Enlarged capillaries extended throughout the fibrous formation. The keloid had ceased growing, it was not inflamed or painful, and was freely movable.

The mother sought advice, fearing "future trouble." Under the circumstances I proposed removal under cocaine anæsthesia, going wide of the growth. At the time appointed, however, operation was refused, and the case thus passed from my notice.

Two other younger children of the household, vaccinated at the same time, presented well-marked scars, but no appearance of hypertrophy.

A SUCCESSFUL PYLORECTOMY ON A MAN IN HIS SEVENTY-FIRST YEAR.

BY ALFRED KING, M.D.,
PORTLAND, ME.,
SURGEON TO THE MAINE GENERAL HOSPITAL.

THIS case of pylorectomy is reported as interesting on account of the advanced age of the patient, who was seventy years six months and fourteen days old on the day of the operation.

Mr. A. B—— was first seen in consultation with Dr. E. J. McDonough on July 7, 1900. He was born December 27, 1829. By occupation he was a mason and contractor. He never weighed over one hundred and thirty-five pounds, but was always well and rugged until two years ago. He then began to have trouble with his stomach, which had slowly grown worse. The symptoms had gradually become those of pyloric obstruction and gastric dilatation. There had been no vomiting of blood or evidence of internal hemorrhage. Recently vomiting of small quantities had become quite frequent, but on every second or third day he threw up several pints. He had been able to attend to his business until within a few weeks, when he had been rapidly losing flesh and strength. Physical examination showed a dilated stomach and a movable, non-adherent tumor, the size of a goose egg, just above the umbilicus. He was informed that his trouble was due to a tumor which obstructed the passage of food, that medicine could not remedy it, and that the only thing that could relieve him was an operation to remove the tumor or make a passage for his food. After consulting with his family he decided to take the chances of an operation rather than live as he was. He according entered the Maine General Hospital July 9, 1900.

On admission to the hospital his pulse ranged from 70–80, his temperature from 98°–99.8°. His urine was scanty, reaction acid, specific gravity 1.028; it contained no albumin or sugar but a large number of hyaline and granular casts.

There were ordered to be given every four hours a hypodermic injection of gr. $\frac{1}{30}$ of sulphate of strychnine and a high enema consisting of two tablespoonfuls of beef peptonoids, one ounce of whiskey, and warm water to make six ounces.

His stomach was washed out at night with hot decinormal salt solution. Long-continued washing was necessary, and even then the returned fluid was quite turbid. It was curious to observe that the tumor, so easily felt but a short time before, just above the umbilicus, was found, immediately after the washing, to be half-way up to the sternum, and that on the following morning, even after the abdominal muscles were completely relaxed by ether, it could not be palpated. On the next morning, July 10th, just before the operation, the stomach was again washed out with hot decinormal salt solution until it returned clear. The operation was performed with the assistance of Dr. John F. Thompson and members of the house staff of the hospital. After the incision was made, careful examination showed that the growth was confined to the pyloric end of the stomach, there being no observable involvement of the lymph nodes or adjacent parts. The case seemed especially suited for Kocher's operation for pylorectomy. This was accordingly done. The gastro-hepatic and gastro-colic omenta were divided between two rows of ligatures on each side well beyond the growth. The non-involved portion of the stomach and the duodenum were clamped off, and the tumor with half an inch beyond on either side was removed. The severed end of the stomach was then closed by three rows of fine silk continuous sutures, one each for the mucous membrane, muscular coat, and peritoneum. The duodenum was then anastomosed by three rows of sutures similarly applied to the lower part of the posterior wall of the stomach, about an inch from the end. The parts were carefully kept clean during the operation by means of packing off pieces and of hot decinormal salt solution. The abdominal wound was closed.

The operation lasted a little over three hours. In spite of the length of the operation and the advanced age of the patient there was but little constitutional disturbance. The pulse ranged from 96–112 and at the close was 104. The respiration varied from 36–44. The amount of ether used during the operation was thirty-three ounces. No stimulant was given during the operation, but at its close, just before the patient was removed from the operating-room, he received hypodermically gr. $\frac{1}{30}$ of sulphate of strychnine, and on reaching his room he received a high enema of two ounces of beef peptonoids, one ounce of whiskey, and warm water to make a pint.

His temperature was taken every two hours for two weeks. It was above 100° but once, and then it was 100.4°. For the first forty-eight hours it was between 98.6° and 100°, but after the second day it did not change from normal.

His respiration was short and accelerated for two days on account of the soreness in the epigastric region, but after that time it was from 22–25.

The pulse gradually dropped from 100 to between 80 and 90 on the second day, but did not reach 72 for ten days.

The amount of urine for the first twenty-four hours after the operation was thirteen ounces. After that the amount was about thirty ounces daily. The kidneys showed no unusual disturbance from the long-continued administration of ether.

There was some vomiting after the operation, but it was never very painful. For two days the vomit was a bloody fluid. On the second day it had an offensive odor from the decomposition of blood. On the second day bile appeared in the vomit. There were occasional nausea and infrequent vomiting for five days, after which time this disturbance was slight and of no consequence.

Nutrition was maintained by enemata containing two tablespoonfuls of beef peptonoids, one ounce of whiskey, and three ounces of warm water every four hours. A little laudanum was added when the bowel seemed irritated. These enemata were employed for three weeks, at the end of which time the patient's stomach could take care of all the nourishment he needed. The use of liquids was started two hours after the operation. One teaspoonful of very hot water was given every half-hour. This quantity was doubled each morning. The lips and mouth were moistened with cold water as occasion required. On the second day a teaspoonful of brandy was given every three hours. On the third day one-half ounce of Eskay's food, prepared without milk, was given every two hours. This amount was also doubled each morning until he had all he wanted. Beef juice was given on the sixth day. On the seventh day an egg beaten up in a malted food was given in the morning and afternoon, and with it a toasted cracker. After the tenth day broths, soups, soft-boiled eggs, and any nourishing foods were allowed, which could not scratch or coagulate or form lumps in the stomach. In the course of a month he was eating any food that could be finely reduced by mastication, that would not scratch, and did not cause any disturbance of the stomach.

The constipated condition of the bowels, which had existed so long from so little food having passed the pylorus, did not continue very long or give much trouble. The nutritive enemata were occasionally expelled. A saline enema on the fourth day produced a good movement. For the first two weeks salts and glycerin enemata, occasionally given, were all that was necessary.

Not very much medication was required. Gr. $\frac{1}{30}$ of strychnine was given every four hours. Gtt. i. of carbolic acid in a teaspoonful of equal parts of cinnamon and lime water every two hours relieved the nausea and checked the gastric fermentation. As he began to take more food, pepsin and hydrochloric acid in glycerin and peppermint water proved beneficial and have since been found useful.

He did not suffer much from pain, but a little morphine or codeine for a few days after the operation relieved restlessness and promoted sleep. Frequent warm alcohol baths also relieved and refreshed the patient.

The condition of the patient to-day, though over seventy-one years of age, and nine months after the operation, is one of comfort, enjoyment, and health. He has good color and is a vigorous man for his age. He has no pain or distress, is able to eat heartily, and do what little work there is about the house. During the last few months he has gained fourteen pounds in weight.

In regard to the portion of the stomach and duodenum removed, it was four inches in length. As there was half an inch of the non-involved portion of the stomach and as much of the healthy duodenum removed, the tumor measured three inches. The entire circumference of the pyloric end was involved. The passage through it was very crooked and less than a quarter of an inch in diameter. The walls measured, after hardening, three-eighths of an inch in thickness. In the recent state they were very hard and unyielding. All peristaltic action was lost.

Excellent microscopic sections from various parts were made by Dr. Walter E. Tobie. The mucous membrane is not much thickened. In the central portion of the tumor the glandular structure is almost entirely destroyed. It has been replaced by a fibrous tissue containing here and there small portions of

glands, small clusters of cancer cells, and chronic inflammatory changes. Its surface is granulation tissue. The mucous membrane at the border of the growth shows hypertrophy of gland structure, superficial necrosis, a few cancer cells, and chronic inflammation. The great thickening is in the muscular portion of the wall. Here the muscular fibres are very widely separated by interstitial connective tissue. In the connective tissue are to be seen a few, but very scattering, groups of cancer cells and chronic inflammatory changes. The peritoneum is not involved. The diagnosis is chronic scirrhus carcinoma of the pyloric end of the stomach.

I have no time to look up statistics, if there are any, on pylorectomies in persons over seventy years of age, but this case, as well as the numerous ovariotomies on women of advanced years, shows that age does not interfere with successful abdominal operations. Nor should age stand in the way of our relieving suffering, promoting happiness, and prolonging human life.

POSTURAL TREATMENT IN THREATENED MISCARRIAGE.

By ALICE M. SMITH, M.D.,

TACOMA, WASH.

The patient, Mrs. M——, primipara, twenty-two years of age and eight months pregnant, on January 10, 1901, at 8 o'clock A.M., began to have labor pains. These continued all day at increasingly short intervals. About 5 P.M. she had a slight "show," and sent for me.

I found her to be a normally developed woman of fairly good physique. She was suffering greatly, and begged for relief. Upon external palpation, I found the head of the fœtus low down in the left iliac fossa, and the buttocks well up in the right flank. Internal palpation discovered that the os uteri pointed directly backward toward the rectum, and it was with much difficulty that I finally determined that the os uteri was dilated to fully 2.5 cm., with the right shoulder presenting.

External and internal manipulations failed to better the position, and after three hours the patient began to show decided symptoms of exhaustion, and, despite the pain, the os uteri did not continue to dilate. The pulse increased from 88 to 124 and to lose force. I gave gr. $\frac{1}{40}$ of strychnine, with satisfactory results. The labor made no progress, and the patient still continued to suffer greatly. I began to fear that I had a serious case to manage. I decided to try what the simple law of gravitation, reinforced by mechanical assistance, would do. Accordingly, I caused the patient to assume the knee-chest position by means of pillows and my personal support, it being under these conditions a most difficult position for her to place herself in. Through the rectum and vagina I now applied digital force. With the examining finger of one hand introduced into the rectum, I reached up behind the displaced cervix and gently but firmly pushed it forward, while, with the index finger of the other hand in the vagina, I endeavored to push the presenting part upward, forward, and to the right (or rather in this position, downward, forward, and to the right), and during the pains I would strive to hold any advantage gained by these measures.

The relief experienced by the patient was almost immediate. The pains became more infrequent and of shorter duration, and would probably have ceased altogether within an hour could she have remained longer in the knee-chest position. When she assumed the recumbent position for rest, the pains began again, but they were of a less agonizing character. Again she assumed the other position, and for an hour we alternated between the two. During nearly all of this time I continued the mechanical assistance as described above. The patient then became so comfortable that I decided it would be safe to leave her in the care of the family for the remainder of the night. Before leaving her, I gave strict orders that the postural treatment be continued until she should be entirely relieved, or until labor should set in with renewed vigor.

The next morning, when I called, I found the patient up, dressed, happy, and as comfortable as the average woman is at that stage of pregnancy. The relief proved permanent. The patient went to full term, and her labor, which occurred February 1st, and the convalescence were normal. The baby, a girl, weighed eight and a half pounds, and has been a sturdy, healthy infant from birth to the present time.

I do not know whether the measures are new or not, but I have never seen them used, nor have I seen them described in any of the medical literature to which I have access.

Uterine Tumors in Infancy, Childhood, and Early Life.—W. Roger Williams says that there are few parts of the body so little liable to tumor formation in early life as the uterus. Myoma: Of the fifty-six cases on his list, only one was under the age of twenty years at the onset. Cancer: This is unknown prior to puberty. Of five hundred consecutive cases the earliest age at onset was twenty-two and a quarter years. Sarcoma: This form of tumor is less rare than the others, but still is exceptional. Holländer reports a case at seven months, and others at one year and a half, two, three, ten, eleven years, etc. A congenital form of mucosal uterine polypus has been met with by Friedländer, Mandach, and Spencer in new-born children. Mandach found it thirty-five times in eighty necropsies. —*Medical Times and Hospital Gazette*, March 23 and 30, 1901.

On the Question of the Advisability of Ligaturing the Jugular Vein in the Treatment of Sigmoid-Sinus Thrombosis.—J. Lacy Firth believes that ligature of the jugular vein in sigmoid-sinus thrombosis need not, in many cases, be regarded as an essential part of the operation, and that it will usually be better practice not to ligate the vein in cases operated upon before embolic abscesses have formed, if a free flow of blood can be established from both ends of the sinus by removal of the thrombi, or if firm, healthy-looking clot is found plugging the sinus at both ends, or at the lower end.—*Bristol Medico-Chirurgical Journal*, March, 1901.

Craniotomy, with the Implantation of Egg-Shell Membrane, for Jacksonian Epilepsy.—William Jones Greer reports a case of this nature of which the salient features were traumatic epilepsy due to a compound fracture of the skull, and the subsequent formation of dense adhesions between brain, membrane, and scalp. The treatment adopted was opening of the dura, which has a curative effect *per se*, possibly by lowering tension, the removal of the diseased motor area in the manner of von Bergmann, and the prevention of adhesions by the insertion of egg-membrane. Four months later, in consequence of a slight injury, the old cicatrix broke down and left a small opening in the scalp, nearly a quarter of an inch in extent, through which could easily be seen a second portion of egg-shell membrane, white and glistening; as it was feared that, by the time this portion would be surrounded by granulations, the old scar might have entirely given way, as it would have very little vascular support until these granulations carried an abundance of life to it,

with fine forceps this second piece of membrane was removed; it came out in its entirety; it was still tough, and stood well the strain of being dragged out, its edges being, apparently, held by granulation tissue. Macroscopically there was no alteration in its structure. Underneath it was a layer of granulations; nothing of the first piece of egg-membrane was to be seen. The small scalp opening soon filled up. Thus the construction of the breach is that next to the brain is the first piece of egg-shell membrane, after that dense fibrous tissue, then scalp.—*Bristol Medico-Chirurgical Journal*, March, 1901.

Resorcin as a Preservative for Suprarenal Extract Solution.—S. Oppenheimer advises the addition of gr. lx. of desiccated suprarenal extract to one ounce of a one-per-cent. solution of resorcin in sterile water. This prevents all putrefactive changes, is non-toxic, and does not in any way impair the full efficiency of the gland.—*Laryngoscope*, March, 1901.

Practical Observations on Infantile Diarrhœa.—F. H. Pirnat divides the treatment into: (1) Hygienic; fresh air, sunlight, bathing, etc. (2) Feeding; lacto-somatose is non-irritating, readily absorbed and assimilated, and does not tax the stomach to the slightest extent. (3) Therapeutic indications are to empty the bowels of all irritating particles of food by calomel gr. $\frac{1}{8}$–$\frac{1}{10}$ doses, or a teaspoonful of castor oil, repeated if necessary every hour. Colonic flushings, stimulants, and opiates are ordered to meet indications.—*The Medical Examiner and Practitioner*, April, 1901.

The Origin of Bile Stones.—F. E. Italia states that attenuated colon and typhoid bacilli are capable of causing a change of the bile in the gall bladder, whereby there is precipitation of the cholesterin, which, cemented by means of mucus secreted by the inflamed mucous membrane, takes on the macroscopic and microscopic appearances of a calculus, with which it is shown to be chemically identical. Chemical action alone does not cause the formation of calculus, neither do dead bacilli, acting as foreign bodies. The path of entrance of the bacilli must be through the bile ducts. It is evident that an infective catarrhal inflammation of the biliary mucous membrane determines the formation of calculi.—*Il Policlinico*, March, 1901.

A Case of Cardiac Suture.—Francesco Lastaria reports the case of a young man who had been wounded in the anterior surface of the right ventricle toward the margin. The author sutured the wound with a continuous suture of about five stitches. Hæmostasis was completely assured. The thorax was explored, and the pleural cavity emptied of all clots and of about a litre of blood. The lung was not wounded. The patient came out of the anæsthetic in good condition, was perfectly conscious, and able to make his deposition to the judge. Intense pain in the thorax developed in the night following the operation, and death occurred at nine o'clock in the morning.—*La Riforma Medica*, March 22, 23, and 25, 1901.

Hyperæsthesia of the Uterus during Pregnancy.—Helga Rüüd reports the case of a pregnant woman who suffered intense pain from abdominal palpation, vaginal examination, and fœtal movements. The patient was obliged to remain in bed, as the upright or sitting position made the pain intolerable. A vasomotor disturbance, consisting of flushing of the face, dilatation of the pupils, and redness of the body, continued throughout pregnancy. Strychnine nitrate was given continuously with a bitter tonic, and various nerve sedatives were tried, but did not relieve the pain, so that morphine had to be given occasionally. There was less pain in the last month of pregnancy. The first stage of labor was intensely painful, some relief being afforded by hot rectal injections. After-pains were unusually severe and called for morphine the first two days after delivery. Ichthyol tampons were applied to the cervix twice a week, from the second week, with intrauterine applications of tincture of iodine, and hot douches were given. The patient was discharged well in three months' time.—*The Woman's Medical Journal*, March, 1901.

Isotonia.—Depierris calls attention to the importance of the theory of isotonia (equality of tension of the blood) in its relation to certain problems in the therapeutics of rhinology. Thus all solutions used in the nose should in a general way have a specific gravity similar to that of the blood; otherwise osmosis is apt to occur. It is well known that the use of solutions of pure water in the nose for any length of time will provoke inflammatory changes which may become permanent. It is, therefore, necessary to estimate carefully the specific gravity of solutions used in conditions of hypertrophic rhinitis, otherwise the efflux of the watery elements of the blood along with certain salts to the nasal mucosa may aggravate the very conditions we wish to remove. In atrophic rhinitis, however, in which there is a lack of moisture, we may purposely make the solutions weak in strength, so that there will be an equalization between their saline percentage and that of the blood. In this way the mucosa will become more freely bathed with moisture and the crust formation be prevented.—*Revue Hebdomadaire de Laryngologie*, March 21, 1901.

Pernicious Anæmia.—William Hunter, as a result of fifteen years' investigations—histological, experimental, clinical, chemical, and etiological—holds that pernicious anæmia is a chronic infective disease of septic origin. In their order of importance the following are the lines of treatment to be followed out: 1. Oral antisepsis, complete in its character, both with regard to diseased teeth, irrespective of absence of pain or discomfort, and to the special lesions of the tongue. 2. Gastric and intestinal antisepsis, in which oral antisepsis is one of the most important measures. 3. Arsenical treatment. Should these measures fail to avert the disease permanently, then four injections of antistreptococcic serum should be given, beginning with small doses (5 c.c.) and taking the precaution, of (1) seeing that the temperature is not in an erratic condition at the time the injection is made, and (2) strengthening the heart's action by means of ammonia and digitalis.—*Medical Press and Circular*, April 3, 1901.

The Pathology and Surgical Treatment of Uterine Tumors in the Nineteenth Century.—W. Roger Williams reviews the history of the pathology and treatment of uterine tumors, too detailed to be satisfactorily abstracted. At the commencement of the twentieth century, he says, the origin of uterine tumors appears to be more closely associated with embryology than with bacteriology. Surgical treatment, by the introduction of anæsthesia, received an extension beyond the dreams of the most visionary. In cases of myomata, the vaginal route and the abdominal both had their advocates. In cases of cancer extirpation was done in France as early as 1801. At the present time the conviction seems to be gaining ground that inasmuch as the disease is seldom limited solely to the uterus, it cannot be eradicated per vaginam, for the object of modern operations is total extirpation of the disease, rather than of the uterus itself. Hence the revival of abdominal total extirpation, in regard to which the author believes that the time has come for giving it serious consideration.—*Medical Press and Circular*, April 3, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, May 11, 1901.

THE CARE OF THE FOUNDLINGS IN NEW YORK STATE.

THE report published in 1897 by the New York county visiting committee of the State Charities Aid Association, in which it was stated that an annual rate of mortality of about eighty per cent. prevailed among the hapless infants admitted to the institution on Randall's Island, thoroughly aroused public attention to the calamitous state of affairs.

Of course the fact is well known that babies, bereft of their mothers and massed together in large numbers under one roof, are particularly difficult to rear—indeed, in the large majority of instances, die with marvellous rapidity. Consequently the problem set the commissioner of charities seemed almost impossible to solve successfully.

The State Charities Aid Association suggested that the placing-out system, as followed with most encouraging results in Massachusetts and Pennsylvania, should be adopted.

The Association for Improving the Condition of the Poor is also taking up the matter. A joint committee of the two associations was formed and submitted to Mr. Keller, the commissioner of public charities for the boroughs of Manhattan and the Bronx, a proposal that a number of the foundlings should be transferred to boarding-houses in the country. The commissioner immediately fell in with the plan, which has been carried out now since April, 1898.

In the twenty-eighth annual report of the New York county visiting committee the system is referred to as follows:

"The plan of boarding, in carefully selected families, in the country, certain of the foundlings who do not thrive in the infants' hospital either on bottle-feeding or by wet-nursing, was continued during the year though the co-operation of the joint committee of the State Charities Aid Association and the Association for Improving the Condition of the Poor, with most satisfactory results. The death rate among the foundlings boarded in families under the care of this committee during the year, notwithstanding the fact that they were selected in many instances from among the most hopeless of the children in the institution, was $19\frac{7}{16}$ per cent."

So satisfactory has this method of rearing these infants proved that the commissioner of public charities for the boroughs of Brooklyn and Queens asked the committee in the summer of 1900 to take charge of the foundlings coming under his supervision. The committee was not able to accede wholly to this request on account of the additional expense, but an arrangement was arrived at by which the Kings County committee took upon itself to supply the necessary funds, and since October 1st the foundlings received in the borough of Brooklyn and Queens have been boarded in families under the care of the committee.

A Catholic society, under the name of the Guild of the Infant Saviour, has recently been formed, which will follow the plan with the foundlings of their faith, already pursued with such beneficial results by the Protestants.

In January, 1901, says the *New York Tribune*, April 28th, the commissioner of charities arranged that hereafter the foundlings should be baptized alternately at the reception ward of Bellevue Hospital, and might be removed directly thence to boarding-houses instead of being first transferred to the infants' hospital, remaining there a longer or shorter period, and then being taken to the country. "The effect of this arrangement has been that the foundlings who since January have been taken directly to their permanent homes are all alive at present."

The boarding-out system is, without doubt, the most humane and rational mode of dealing with foundlings, and should wherever possible be followed. The large institutions, like the one at Randall's Island, might be classed in the same category as Sing Sing Prison, relics of the dark ages.

VICE AND THE CHURCH.

Leslie's Weekly, April 6th, contains a forcible letter from Dr. William Lee Howard, of Baltimore, with regard to the attitude of ministers of all denominations upon the subject of vice. Dr. Howard takes as the text for his remarks a contribution of Bishop Doane's to the same journal of March 9th, in which he deals with the question as to how vice in our cities can be suppressed, and urges that the only means of attaining this object is religion and the consequent moral rehabilitation of the vicious. Dr. Howard asserts that ministers misconceive the real cause of vice, and that behind the ignorance or indifference of the church arises much of the vice seen in our midst, and that it is owing to their want of knowledge of biological and physiological laws that they unite couples who communicate, transmit, and perpetuate physical and mental unhealthy conditions. Dr. Howard seems to be of the opinion that clergymen should refuse to marry such persons. While it is undoubtedly true that clergymen are too apt to consider the matter entirely from their own point of view, and to ignore physiological facts and problems, yet the fact must be borne in mind that their teaching and training tend to make them regard the situation from a spiritual and moral rather than a mental or physical aspect, and further, that they are not qualified to judge with regard to the fitness or otherwise of those wishing to marry. If laws are to

be made to restrict marriage, they must be made with the concurrence of a majority of the population, of which the clergy, as well as the medical profession, are, after all, but a small part. The people at large must be educated to appreciate the evils resulting to the race from the union of the obviously unfit. When this comes to pass, laws restricting marriage will be enacted without opposition. It is within the physician's province thus to educate both the clergy and the general public.

THE CAUSATIVE AGENT OF VARIOLA AND VACCINIA.

That smallpox is a specific infectious disease has long been recognized, although doubt has prevailed as to its relation to cowpox and as to that of both to vaccinia. Now, it may be safely reasoned that the development of vaccinia in human beings as a result of inoculation with cowpox, accidentally or intentionally, is proof of the identity of the causative factors of both conditions, while the protection from smallpox conferred by vaccinia is at least circumstantial evidence of close relationship, if not actual identity, between cowpox and smallpox, the former being probably an attenuated or modified variety of the latter. Further, calves have been successfully inoculated with smallpox, with the development of conditions identical with those of cowpox.

Efforts have for a long time been directed to the isolation of the hypothetical exciting agent of variola and its modifications. Sacco, in 1809, found granules in vaccine lymph; Beale, in 1863, minute transparent or hyaline particles; Hallier and Zurn, in 1867, and Keber, in 1868, micrococci; Chauveau and Burdon-Sanderson, in 1868, minute granular bodies; Cohn, in 1872, again micrococci; and since then numerous observers have found different organisms. L. Pfeiffer, in 1887, although he noted the presence of both fungi and bacteria, expressed the belief that the specific agent was a sporozoon. Renault, in 1881, had already described, in the epithelial cells of the vesicles in cases of vaccinia and variola, peculiar bodies that he regarded as parasitic; and subsequent observers, including also Pfeiffer, have made further studies that strengthen the probability that the cause of these disorders is really a protozoon. It is not unlikely that many of the bodies described are merely accidental, and experience has amply shown that if they be removed—as occurs in the present methods of preparing glycerinated lymph—the usual unpleasant complications of vaccinia are generally avoided.

In a recent communication Funck (*British Medical Journal*, February 23, 1901, p. 448) adds further evidence in support of the view that the protozoon described by Pfeiffer is the actual cause of variola and vaccinia. He found that, after permitting autosterilization of glycerinated lymph, he was still able to excite characteristic pustules, whose contents likewise were sterile. Microscopical examination of fresh vaccine disclosed the presence of clear spaces, and of dry and stained preparations of vaccine and of the contents of variolous pustules, the presence of ovoid transparent vacuoles resisting the action of aniline stains. The parasite appeared in three forms, representing different stages in its evolution. The designation sporidium vaccinale is proposed for the organism, which can be studied conveniently only in fresh preparations in emulsions made with bouillon or physiological salt solution. By fishing out the bodies with a platinum spatula, making an emulsion with a drop of bouillon, and inoculating a calf, it was possible to develop characteristic pustules. The animal thus treated further was found to be insusceptible to subsequent inoculation with vaccine.

Copeman (*British Medical Journal*, February 23d, p. 450) has detailed an ingenious method for cultivating the supposed microbe of variola and vaccinia. Having concluded that the culture medium must be a living one, he was led to introduce into the peritoneal cavity of rabbits and dogs collodion capsules containing a small amount of beef broth inoculated with a trace of glycerinated lymph free from microbes. On staining with methylene blue and examining microscopically film preparations of such capsules as remained unruptured, numerous zoöglœa masses were visible, made up of bodies resembling spores, and only the periphery of which took the stain. The fluid contents of the capsule were found also capable of inducing the typical eruption of vaccinia in calves, although the contents of control capsules, placed in test tubes partly filled with beef broth and exposed to body temperature, yielded no result. Apparently similar microorganisms, often in extraordinary numbers, were found also in the epithelium of vesicles in vaccinia in the calf, and also in the contents of the vesicles of human smallpox.

TWENTY-EIGHTH ANNUAL REPORT OF THE NEW YORK COUNTY VISITING COMMITTEE UPON BELLEVUE HOSPITAL.

This report for Bellevue Hospital for the year 1900 is of more than ordinary interest because of the bright light which has been recently thrown upon the management of the institution, owing to the scandals which arose in connection with the alleged ill-treatment of the insane within its walls. The report of the visiting committee, proceeding as it does from an independent source, should be at the present juncture of especial value, it being likely neither to gloss over nor to exaggerate defects. It is somewhat reassuring consequently to observe that in the opinion of the committee decided progress seems to have been made in many important respects with regard to the general conduct of the institution.

For example, since 1899 the unpaid or convalescent helpers have been reduced in number from one hundred and eighty-seven to sixty-one, while workhouse help has been abolished entirely. In 1870, when the capacity of the institution was but seven hundred and fifty beds, it contained seven hundred and seventy-nine patients, the nursing was carried on by workhouse women, and the condition of the place is said to have been such that it was considered a degradation for any

decent woman to undertake the duties. The wards, too, are kept as clean as is possible in so antiquated a building.

The fact, however, remains as obtrusive as ever, that the conglomeration of, for the most part, out-of-date erections known as Bellevue Hospital is neither adequate nor adapted to the purposes for which it is used.

The following statement of the committeee should be alone sufficient to demonstrate the need for root-and-branch reform:

"The most serious and urgent need at Bellevue Hospital is that of proper quarters for the employees. The employee should be of a class that will care for patients as they should be cared for, and if the quarters are miserable the class of employee is apt to be the same. . . . Some of the employees sleep in the basement of the hospital, some in the wards, others are scattered here, there, or anywhere. There is not a single sitting-room for any of them in any part of the building. How can proper persons be content to live in this forlorn manner?"

It is undoubtedly of the first importance, if a hospital is to do good work, that both patients and employees should be housed decently. Therefore, the first step to be taken to render Bellevue Hospital beneficial to the sick and injured, and efficient as a training-school for nurses, would appear to be to raze the existing incongruous structures, and to erect in their stead a well built and equipped modern hospital.

SURGICAL TREATMENT OF MIGRAINE.

Certain analogies are apparent between epilepsy and migraine, both being considered nerve-storms, the one involving especially the motor, the other especially the sensory, sphere. Further, both may be inherited, both occur in paroxysms, both may be preceded by an aura, both may exhibit a hemiplegiform, a paraplegiform, or a monoplegiform character, and, finally, the one disease may alternate with the other, in the same family, between parent and child, between brother and sister, and even in the same individual. From the practical point of view it may be added that both are at times most resistant to treatment, although palliation can usually be afforded by means of bromide. In view of this last fact a statement made recently by Whitehead (*British Medical Journal*, February 9, 1901, p. 335), to the effect that during the last twenty-five years he had never failed to treat successfully the most inveterate and severe cases of migraine by introducing an ordinary tape seton through the skin at the back of the neck, is worthy of respectful attention. Some of the cases have been of excessive intensity, and all had been previously under medicinal treatment without relief. In one, it is related, the attacks had recurred every few weeks for six years, and were attended with complete prostration, violent headache, and nausea and vomiting for periods of from twelve to twenty-four hours. The introduction of a seton was followed by cessation of the attacks.

In performing the slight operation the skin at the back of the neck is grasped between the fingers and the thumb of the left hand, and the tissues are transfixed behind the fingers with a long-bladed scalpel. Before the knife is removed a long probe provided with a suitable eye is passed through the wound, following the knife as a guide, and the scalpel is withdrawn. A piece of ordinary household tape, one-half inch wide, is then attached by a ligature to the eye of the probe, which is pulled through the wound, bringing the tape with it. Four inches of tape are left free at either side, and the ends are tied together to prevent the tape from being accidentally withdrawn. Each day the tape should be moved from side to side. If performed with moderate dexterity, the operation need occupy only half a minute, and nitrous oxide will suffice as an anæsthetic. The seton should be worn uninterruptedly for three months at least in the first instance, and a second seton should be introduced if the symptoms recur. Continuing the analogy spoken of at the beginning of these remarks, the application of the same measure to the treatment of epilepsy naturally suggests itself; and although the procedure is one that does not inherently commend itself, nevertheless its trial in the conditions under consideration would be wholly justifiable.

News of the Week.

Dr. A. O. J. Kelly has been elected professor of the theory and practice of medicine in the University of Vermont.

Dr. Clarence A. Veasey has been elected ophthalmic surgeon to the Methodist Episcopal Hospital of Philadelphia.

Philadelphia Hospital.—An active movement is on foot to separate the almshouse from the Philadelphia Hospital, extensive improvements to which are in contemplation.

Private Hospital for Contagious Disease.—The movement for the erection in Philadelphia of a hospital for contagious diseases for private patients has received additional impetus. Encouraging reports have been received from various sources, and it is said a site for the buildings has been secured in the suburbs, convenient of access.

American Proctologic Society.—The third annual meeting of this society will be held at the Hotel Aberdeen, St. Paul, Minn., on June 4 and 5, 1901, under the presidency of Dr. James P. Tuttle, of New York. The secretary is Dr. William M. Beach, of Pittsburg, Pa.

Dinner of the Harlem Medical Association.—This society gave its annual reception and dinner at the Hotel Majestic on Wednesday evening, April 17th. Covers were laid for two hundred and fifty guests. The dinner, which was at 8:30, was preceded by a reception in the parlors of the hotel and was followed by an entertainment, speaking, and an informal dance. Speeches were made by Drs. John A. Wyeth, A. G.

Gerster, M. R. Richard, and Emil Mayer, the Rev. George R. Van De Water, and Dr. L. J. Ladinski, chairman of the dinner committee. The officers of the association are: *President*, Dr. M. R. Richard; *Vice-President*, Dr. J. B. Lumbard; *Secretary*, Dr. W. K. Luckett; *Treasurer*, Dr. W. H. Stewart.

Cecil County (Md.) Medical Society.—Dr. Joseph W. Wallace, of Chesapeake City, has been elected *President*, Dr. John H. Jamar, of Elkton, *Treasurer*, and Dr. H. P. Hinchcliffe, *Secretary*.

Philadelphia Polyclinic and College for Graduates in Medicine.—Dr. Samuel D. Risley has resigned from the chair of ophthalmology and has been elected emeritus professor. Dr. William Campbell Posey has been elected his successor.

The New York Academy of Medicine.—At the meeting to be held on Thursday evening, May 16th, there will be a memorial address on the late Dr. S. S. Purple, formerly president of the Academy, by Dr. Stephen Smith; papers on "Sitophobia of Enteric Origin and on Syphilis of the Liver," by Dr. Max Einhorn; on "The Intestinal Intoxication Occurring in Mucous Colitis in Young Children," by Dr. Henry Koplik. Discussions by Drs. Jacobi, Chapin, Northrup, Southworth, and others.

The New York State Hospital for the Care of Crippled and Deformed Children, at Tarrytown, N. Y., will be opened on Friday, May 17th, from 3 to 5 P.M. The Right Rev. Henry C. Potter, D.D., president of the hospital, will preside. Short addresses will be made by Prof. Robert F. Weir, M.D., of Columbia University, Prof. A. Alexander Smith, M.D., of the University of the City of New York, and Prof. William M. Polk, M.D., of Cornell University.

The Edward N. Gibbs Memorial Prize Fund.—The New York Academy of Medicine has received $10,000 from Mrs. Sarah Barker Gibbs and Miss George Barker Gibbs, for the establishment of the Edward N. Gibbs Memorial Prize Fund, the income to be awarded triennially to the physician of regular standing in the medical profession of the United States of America who shall present the best original essay upon the etiology, pathology, and treatment of the diseases of the kidney.

An International Sanitary Treaty.—Two South American states, Argentina and Uruguay, have made a treaty of sanitary alliance and protection as regards infectious diseases, especially bubonic plague. It provides for mutual inspection and quarantine arrangements sufficient to protect either country from invasion of disease from the other, without any undue interference with communications or commerce. It would be well if the example thus set were imitated by other nations.—*British Medical Journal.*

An Insane Doctor Stabs His Fellow Patients.—A despatch to *The Sun* from Stockholm says that Dr. Nehrman, a patient in a small private hospital at Grenna, suddenly became mad recently and stabbed a widow and three girls who were inmates of the place, killing one of the latter. He ran about the streets throughout the night and stabbed five persons, three of whom were dangerously wounded. He was ultimately captured and imprisoned. One of the women killed was a nurse in the institution, a Miss Von Deuben, who is said to have served some years ago in a hospital in this city.

Nurses' Home of the Presbyterian Hospital.—Work on the Home for Nurses to be erected by the Presbyterian Hospital on East Seventy-first Street, between Park and Madison avenues, is delayed owing to a temporary injunction granted in the supreme court last month. Application has been made to have the injunction made permanent. A resident of Seventy-second Street, directly in the rear of the new building, objected to it, and he was joined by neighbors who declared that the erection of the home was in violation of restrictions placed in the deeds of property in the block. In the application for the injunction it is declared that the home will be "noxious and offensive."

Medical Society of the State of New York.—At the ninety-fifth annual meeting of the State Society in Albany last winter, it was decided to hold a semi-annual meeting in the city of New York early in October. Final arrangements have been made for this meeting, which will be held at the New York Academy of Medicine on Tuesday and Wednesday, October 15 and 16, 1901. There will be a morning and an afternoon session on Tuesday, and Tuesday evening the society will tender its members and guests a reception to be held at Delmonico's. There will be a morning and afternoon and an evening session on Wednesday. These sessions will be devoted entirely to scientific work. Members wishing to read papers are requested to communicate with Dr. Nathan Jacobson, 430 South Salina Street, Syracuse, N. Y., and information of any other nature can be obtained from Dr. Frederick C. Curtis, secretary, 17 Washington Avenue, Albany, N. Y., or from Dr. Frank Van Fleet, associate secretary, 63 East Seventy-ninth Street, New York City. In order to increase the facilities for the admission of permanent members of the society, it was voted at the last annual meeting that each county society should be allowed to send five times the number of delegates it had formerly sent to the State society. These delegates are elected for a term of three years, and are eligible for permanent membership if they register twice during that time. This will make the number of delegates from the county society to the State society seven hundred and fifty in all, or one delegate for every eight or nine members of county societies, without increase of expense to the county societies.

The Plague.—A Japanese woman died of the bubonic plague in Honolulu on March 28th, but no other cases have occurred so far as the authorities have ascertained. An increase of both plague and smallpox is reported from Manila. Most of the Manila cases are among the Chinese. Consul McWade at Canton reports that in the village of Chan-Tsin, twelve miles

west of that city, there are from twenty to thirty deaths daily from plague. The population of the place is only about four thousand. Plague riots have occurred at Sialkote, where the military has been summoned to suppress the mob. The people have risen against the authorities, and in a struggle between the plague officer and his assistants on the one side and rioters on the other twenty villagers were killed. Twenty-five villages are in revolt in the district, and several hospital assistants have been killed or wounded.

Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases.—Governor Stone has appointed Dr. L. Webster Fox a trustee on behalf of the State.

Typhus Fever is reported to be prevailing extensively in Mexico City and Vera Cruz, and quarantine has been declared at the Texas border against passengers from Mexico, and at Havana against those coming from Vera Cruz.

Cottage Hospitals in Canada.—Countess Minto, wife of Canada's governor-general, has written a letter to the mayor of Ottawa stating her willingness to become the head of a movement to establish cottage hospitals throughout Canada.

Emergency Hospital at Union Hill, N. J.—An emergency hospital was opened on Sunday last in the old Gardner mansion, at Union Hill, N. J. The house was purchased by a society of women with money realized from entertainments, fairs, and subscription lists. It has twenty-five beds, a well-equipped operating-room, a staff of trained nurses, and a resident physician and surgeon.

The Infectiousness of Cancer.—We regret to learn that Dr. Joseph Eisen, of San Francisco, with whose excellent work in the study of the supposed micro-organism of carcinoma our readers are familiar, has been operated upon in St. Luke's Hospital in that city for cancer. The operation was successful and the patient is recovering. Dr. Eisen believes that he became inoculated with the cancer microbe while studying the germs through the microscope.

The Health of New York State.—According to the report of the State board of health, there were during March 11,913 deaths in the State from all causes and a death rate of 19.2; a decrease from a daily rate of 394 in February to one of 384. During the first three months of the year there have been 35,529 deaths, including delayed returns, a daily rate of 395, which exceeds that of the same months in 1900 by 12 deaths daily. Grippe is estimated to have caused during March about 1,500 deaths, the same as in February.

Resignation of Dr. Tracy from the Health Department.—Dr. Roger Sherman Tracy, the registrar of the Bureau of Vital Statistics of the New York health department, tendered his resignation to the health board May 1st. It was accepted. No successor was appointed. The board granted Dr. Tracy a pension of $1,200 a year. His salary was $4,000. Resolutions of regret at his retirement and praising him for his services were passed. Dr. Tracy had served thirty years in the department, having been appointed an inspector of the health department on October 7, 1870.

Philadelphia Polyclinic.—Dr. Ralph W. Seiss has resigned as professor of diseases of the ear, and Dr. Francis R. Packard has been elected to fill the vacancy. Dr. B. M. Randolph, at present in charge of the department of pathology at the Richmond Medical College, has been elected dean in succession to Dr. Packard and also director of the laboratories.

An Inspection of the State Institutions.—Governor Odell is arranging to visit the fourteen State hospitals for the insane, the sixteen State charitable institutions, the three State prisons, and the State reformatories. The purpose of these visits is to enable the governor to familiarize himself with the work and needs of the State institutions, the number of employees needed, and the extent of their compensation.

War on Mosquitos.—The South Orange (N. J.) Village Improvement Society will try to rid that community of mosquitos during the coming season, and has appointed a committee which will seek to carry its resolutions into effect. It is the intention of the society to advocate the abandonment of rain barrels, the screening of water tanks in houses, and the placing of a thin layer of crude oil in cesspools and in pools of stagnant water which it is not practicable to drain. A free lecture on mosquitos will be delivered in the village shortly by Prof. L. O. Howard, of the Department of Agriculture, Washington.

Ambulance Races.—The young men in charge of the hospital ambulances in this city decidedly need looking after, if the accounts of their varied performances which the daily papers give are not grossly exaggerated. About once a week an ambulance surgeon diagnoses a case of fracture of the skull or of apoplexy as "a drunk," and refuses to take the patient, who subsequently dies—not from alcoholism. Not long since an ambulance surgeon refused to enter an apartment house where there had been a fire, to see a person who had been injured, alleging that the place was wet, and he might catch cold. But, not content with simple neglect of duty, the ambulance surgeons have of late taken to the sport of racing on the city streets. The papers of Sunday last contained an account of a race between the auto-ambulances of Roosevelt and the Presbyterian hospitals, in which the lives of two patients in the ambulances and of hundreds of persons in the streets were placed in peril. According to *The Times*: "There has been heated rivalry between the two hospitals over these auto-ambulances. Each vehicle is of the best pattern and can be run at a terrific rate of speed, as was shown last night. Other automobiles that tried to keep up with them were easily distanced. The last time a race occurred between the auto-ambulances of these hospitals the chauffeurs fought over the race and the merits of their machines, and got arrested. The race last night began at Fifty-seventh Street and Fifth Avenue, when the ambulances met. Dr. Linden had a destitute patient

from the Presbyterian Hospital, William Burden, seventy years old, whom he was transferring to Bellevue. Dr. Royce had Fanny Johnson, a colored woman, ill with grippe. She was a transfer patient. As soon as the chauffeurs saw each other's vehicles, they let their levers out to the fullest extent and the auto-ambulances, with bells a-clang, shot out past all the rest of the vehicles on the avenue. They fairly leaped along, and other chauffeurs and drivers and pedestrians got out of the way as quickly as possible. At Twenty-sixth Street and First Avenue the ambulances shot over the car tracks dashboard even with dashboard. Neither could gain, but the Roosevelt Hospital ambulance was on the inside. This gave the right of way. There is only room for one vehicle to pass through the gate at a time, and this gave the race to Roosevelt Hospital."

Philadelphia Neurological Society.—At a stated meeting held April 22d, Dr. Alfred Gordon exhibited "A Case of Tea Intoxication with Spinal Symptoms." The patient was a woman who for many years had drunk tea in excessive amounts, sometimes in the form of an infusion, at other times in that of a decoction, at one time in the enormous amount of forty-five cups daily. At such times she of course took little other nourishment, and she was consequently quite anæmic. She presented among other things ataxia of gait and station, with exaggeration of knee jerks and other reflexes, together with areas of anæsthesia and other symptoms suggestive of hysteria. Distinct improvement followed upon abstinence from tea, but the patient was unable to resist temptation, and a return to her previous excesses was attended with an exacerbation of the symptoms. The question was raised whether the symptoms of spinal disease could be attributed to tea intoxication, to the secondary anæmia, possibly to lead intoxication, or some other obscure form of metallic poisoning. Dr. J. Chalmers Da Costa exhibited "A Case of Trichiniasis" in a young man who had apparently been well until after being struck on the calf of the leg by the pedal of a bicycle in the course of a long ride, without the development of any external laceration. Subsequently he took up his residence with a milkman, and he indulged largely in fried pork. He presented himself on account of swelling of the muscles of the leg, which stood out with marked distinctness. After a time the thigh of the corresponding side also became enlarged. The enlarged muscles were extremely hard and suggestive of pseudo-hypertrophic paralysis, and as there had been no premonitory symptoms referable to the gastro-intestinal tract or in other muscular situations than the one calf, trichiniasis was tentatively excluded. Examination, however, of a bit of excised muscle disclosed the presence of encapsulated trichina spiralis in large number. Examination of the blood disclosed at first an absence of leucocytosis, although this subsequently developed in moderate degree, but without increase in the eosinophile cells. Dr. Max H. Bochroch exhibited "A Case of Rhizomelic Spondylosis." The patient was a young medical man who had had several attacks of rheumatism and also an attack of gonorrhœa. He exhibited marked rigidity of the spinal column, with pain on attempts at active or passive motion, impaired mobility at the shoulder-joints and the hip-joints, with exaggerated knee jerks, girdle sense, and other paræsthesiæ. Drs. William E. Hughes and William G. Spiller reported "A Case of Severe Anæmia with Changes in the Spinal Cord." . During life the existence of spinal lesions was not suspected, but post-mortem examination disclosed diffuse sclerosis of the cord, particularly in the upper portion, with thickening of the coats of the blood-vessels. Dr. W. W. Keen read a paper entitled "Report of a Case of Secondary Suture of the Posterior Interosseous Nerve, with Complete Re-establishment of Function." The nerve had been divided accidentally through an incised wound inflicted by an axe, and the most conspicuous symptom was weakness of the extensors of the fingers, particularly the central ones. After an interval of three months the ends of the nerves were exposed, freshened, and united, and re-establishment of function was noted within little more than a week, progressing until almost perfect. Injuries of this nerve are extremely rare. Dr. David Riesman reported "A Case of Intermittent Claudication." The patient was a man addicted to excess in the use of tobacco both by smoking and by chewing, who for a number of years suffered from pain and paræsthesia in one leg, with interference in locomotion after walking even a short distance. In the attacks pulsation could not be detected in the peripheral vessels of the affected member. The urine contained albumin, but no tube casts could be found. Some relief followed treatment with massage, mercury, and iodide, although no history of syphilis could be elicited. The disorder is dependent upon obliterative endarteritis, intensified perhaps by arterial spasm. It has been observed also in lower animals and was first described by veterinarians in horses. Its characteristic symptom is the intermittent limping, with loss of pulsation in the peripheral vessels.

The Minnesota Marriage Law.—The so-called "Chilton marriage law," as finally passed by the Minnesota State legislature, provides that "no woman under the age of forty-five (45) years or man of any age, except he marry a woman over the age of forty-five (45) years, either of whom is epileptic, imbecile, feeble-minded, or afflicted with insanity, shall hereafter intermarry or marry any other person within this State. It is also hereby made unlawful for any person to marry any such feeble-minded, imbecile, or epileptic person or any one afflicted with insanity." State officials are forbidden to issue marriage licenses, and clergymen and others are forbidden to solemnize marriages in cases in which either of the parties is afflicted with any of the diseases mentioned. Violation of any of the provisions of the act is punishable by a fine of not more than $1,000, or by imprisonment in the State prison for not more than three years, or by both such fine and imprisonment.

A School for Backward Children, with provision for classes not exceeding seventy-five pupils, has been established in Philadelphia by the Civic Club and the

Public Education Association, and whose support the city is being asked to undertake. Only children that do not get along in the regular classes are received, while those sufficiently defective to be worthy of admission to institutions are not accepted. The results of the operation of the school have thus far been most satisfactory, some of the pupils having been returned to the public schools. The system of instruction comprises individual training, and includes, in addition to instruction in the ordinary elementary school branches, manual and physical exercises.

The Connecticut Medical Society.—The next annual meeting of this society will be held at Hartford on May 22d and 23d, and not on May 15th and 16th as had been announced.

Smallpox in Sydney.—Sydney, New South Wales, is again the unfortunate victim of an epidemic. This time it is suffering from smallpox, which is a disease that Australia has taken great pains to keep at bay.—*The Hospital.*

The Salem County (N. J.) Medical Society has elected the following officers for the ensuing year: *President*, Dr. E. E. De Grofft; *Vice-President*, Dr. B. A. Waddington; *Secretary and Treasurer*, Dr. H. Chavanne; *Reporter*, Dr. W. H. Carpenter; *Censor*, Dr. N. S. Hires.

Dr. Adami at the Brooklyn Medical Club.—Prof. J. George Adami, of McGill University, Montreal, will deliver an address under the auspices of the Brooklyn Medical Club, on Friday, May 17th, at 8:30 P.M., in the Medical Library Building, 1313 Bedford Avenue. His subject will be "The Medical Aspect of Heredity."

The Medical Society of the State of North Carolina.—The forty-eighth annual meeting of this society will be held at Durham on May 21, 22, and 23, 1901, under the presidency of Dr. Julian M. Baker, of Tarboro. The secretary is Dr. George W. Pressly, of Charlotte, and the committee of arrangements is composed of Drs. A. G. Carr, N. P. Boddie, and N. M. Johnson, of Durham.

The Indiana State Medical Society will meet in its fifty-second annual session at South Bend, on May 15, 16, and 17, 1901, under the presidency of Dr. G. W. McCaskey, of Fort Wayne. The secretary is Dr. F. C. Heath, of Indianapolis. Dr. John A. Wyeth, of this city, will deliver an address on the evening of May 16th.

Births, Deaths, and Marriages in Great Britain.—In Great Britain in 1899 the marriages reached the highest number recorded since 1876, aggregating 262,834, or 16.5 per 1,000. The births numbered 928,646, equal to 29.3 per 1,000. There were 37,124 illegitimate children born; the deaths numbered 581,799, equal to 18.3 per 1,000, and there were 2,844 suicides.

The American Medico-Psychological Association.—The fifty-seventh annual meeting of this association will be held in Milwaukee, Wis., on June 11, 12, 13, and 14, 1901, under the presidency of Dr. P. M. Wise. The annual address will be delivered by Warren P. Lombard, professor of physiology in the University of Michigan. The subject will be "Re-enforcement and Inhibition of Nervous Processes." The committee of arrangements of the American Medico-Psychological Association hopes to obtain from the railroads the privilege of a stop-over at Milwaukee on the return trip from St. Paul by those who first attend the meeting of the American Medical Association at that point and who desire to attend the Milwaukee meeting later.

Austrian Census.—Preliminary reports of the Austrian census, taken on December 31st last, give the population of Austria as 26,107,304 and that of Hungary as 19,203,531. The total population of the empire, including Bosnia and Herzegovina, is probably about 47,000,000, an increase of a little over nine per cent. since 1890. The population of Vienna is 1,635,647, and that of Budapest 729,383.

Physiologists' Congress.—The International Congress of Physiologists will hold its fifth meeting next autumn at Turin, Italy. Prof. Angelo Mosso is the president and in addition to three general secretaries for each of the three official languages, French, German, and English, Prof. Frederic S. Lee, of Columbia University, secretary of the American Physiological Society, will act as secretary in America. Any one who wishes to become a member of the congress—the membership of which is open to any member of a physiological or purely scientific society—or any person proposed by a national committee should communicate with Dr. Z. Treves, Corso Raffaelo 30, Turin, before the beginning of August, at the same time forwarding a fee of ten francs, which is to go toward the expenses of the congress.

Immigration to Cuba.—The division of the insular affairs of the United States War Department has just published the following facts with regard to immigration to Cuba for the calendar year 1900: The total number of immigrants arriving at Havana during 1900 was 14,578. The Chinese immigrants numbered 226; 17 from the United States, 18 from the United Kingdom, 106 from China, 16 from British North America, 62 from Mexico, and 7 from South America. The Filipino contribution numbered 7. Six Japanese and 3 Koreans came from the United States. Most of the immigrants were Spanish, the total number being 12,935, of whom 12,094 were from Spain, 396 from Mexico, and 346 from the United States. The immigration from other nations was: English, 148; French, 195; Italian, 304; Mexican, 225; German, 99.

Census of India.—According to the Bombay correspondent of the London *Lancet*, contrary to expectation, many places in India show an actual diminution in population as compared with the census of 1891. On the other hand, there are several instances of extraordinary urban increase. Howrah, on the opposite bank to Calcutta, shows an increase of 34 per cent.; Rangoon, an increase of 29 per cent.; and Naina Tal,

an increase of 45 per cent. Delhi, Cawnpore, Jubbulpore, and Lahore also show increases, but in Lucknow, Benares, Bangalore, and Bombay there have been small declines.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending May 4, 1901. Assistant Surgeon B. L. Wright ordered to the *Massachusetts*, May 1st. Assistant Surgeon S. S. Rodman detached from the *Adams* and ordered to the *Alert*, May 11th. Surgeon H. L. Law, retired, detached from the recruiting rendezvous, Buffalo, N. Y., and ordered home.

Philadelphia County Medical Society.—At a stated meeting held April 24th, Dr. John B. Roberts demonstrated "A Case of Insertion of an Artificial Vitreous after Evisceration of the Eyeball," illustrating the mobility of the globe and avoidance of the characteristic appearance of an artificial eye. Dr. Roberts demonstrated also "A Case of Rhinoplasty after Loss of the End of the Nose." The nose had been almost entirely destroyed by the application, on the advice of an irresponsible practitioner, of some actively caustic agent, and the parts were restored and a satisfactory nose was formed by means of flaps obtained from the adjacent cheek. Dr. J. Dutton Steele read a paper entitled "The Present Aspect of the Antitoxin Treatment of Diphtheria," in which he rehearsed statistics showing the marked reduction that has steadily taken place as a result of the constantly increasing employment of the antitoxin. Dr. Steele laid particular stress upon the importance of immunizing injections for those exposed to infection and in the presence of epidemics that persist in spite of all of the usual precautions. Emphasis was placed also on the demonstrated possibility of infection from diphtheria bacilli in the healthy throats of apparently uninfected individuals. Dr. F. A. Packard read a paper on "The Clinical Manifestations of Diphtheria," in which he pointed out the atypical character of the symptoms and their deviation from the clinical picture described by earlier writers. The differential diagnosis can be made only by bacteriological examination, as any and all of the clinical phenomena may be present quantitatively and qualitatively in any of the disorders resembling diphtheria. Dr. J. P. Crozer Griffith read a paper on "The General Treatment of Diphtheria," in which he discussed, apart from the use of antitoxin, the employment of local applications and the administration of such remedies as calomel and tincture of iron chloride. Dr. A. C. Abbott spoke of "The Bacteriology of Diphtheria," pointing out that the so-called pseudo-diphtheria bacilli are probably in all instances true diphtheria bacilli of attenuated virulence, but which may nevertheless become a source of danger by a return of their virulence or their reception into the bodies of susceptible individuals. Dr. Richard M. Pearce discussed "The Pathology of Diphtheria," and illustrated his remarks with lantern slides. He exhibited especially sections of the myocardium and of the kidneys, showing the profound changes that take place in both of these organs even at a comparatively early date. Dr. Joseph McFarland spoke of "The Mode of Action of the Antitoxin," in which he assented to the view that this is largely if not wholly of a chemical nature. Dr. M. Howard Fussell spoke of the importance of early treatment and the employment of adequate doses in order to secure the desired result.

The Late William H. Draper, M.D.—At a special meeting of the medical board of St. Luke's Hospital the following memorial notice of the death of Dr. William H. Draper was adopted:

"The medical board of St. Luke's Hospital desires to express its deep sense of loss in the death of their beloved associate, Dr. William H. Draper. His services began with the opening of the hospital in 1857, when he was appointed attending physician, the other members of the medical staff being Dr. Alonzo Clark, Dr. T. G. Thomas, and Dr. C. F. Heywood. In 1867 he resigned, and was appointed consulting physician, and held this position up to the time of his death, having retained an intimate connection with the interests of the hospital for the long period of forty-four years. Dr. Draper possessed intellectual, social, and moral qualities that made him in many ways an ideal physician. He was a careful and thorough diagnostician. His sound judgment gave him the confidence of his patients and his professional brethren, while his kindliness of heart and a peculiar charm of manner won him hosts of friends. His distinguished career will be remembered with pride by the profession which he adorned, but those who enjoyed the pleasure of a long friendship with him will always feel that the man himself was the chief attraction. The sterling principles of his character, his uprightness, his loyalty, and his lovableness were the qualities which made his friends love him even more than they admired his great ability as a scientific physician. Farewell for a time, dear friend. We mourn for you but for a short time only. The old friendships will be renewed surely. V. H. Norrie, M.D., *Secretary.*"

Obituary Notes.—Dr. Irving C. Rosse, of Washington, died in that city on May 3d, at the age of fifty-four years. He was a native of Maryland and was a graduate of the medical department of the University of Maryland in the class of 1866. He served in the medical corps of the United States army from 1863 to 1874, and was surgeon of the United States steamer *Corwin* on two polar expeditions. He was a member of the American Medical Association, of the Medical Society of the District of Columbia, of the American Anthropometric Society, of the American Neurological Association, and of the New York Medico-Legal Society. He was a ready writer and was a frequent contributor to encyclopædic and periodical literature.

Dr. Abraham Deyo died at Gardiner, Ulster County, N. Y., on May 4th, at the age of seventy-one years. He was a graduate of the College of Physicians and Surgeons, Columbia College, N. Y.

Dr. Samuel K. Lyon, of this city, died on Friday of last week very suddenly of hæmoptysis, at the age of sixty-three years. He was a graduate of the College of Physicians and Surgeons, Columbia University, New York, in the class of 1866. He was surgeon to

the police department for over thirty years. He was a member of the County Medical Association, the County Medical Society, the Academy of Medicine, and the Physicians' Mutual Aid Association.

Dr. Harold Snowden, editor of the Alexandria, Va., *Gazette*, and a veteran of the Civil War, died at his home in that city on May 4th at the age of sixty-five years.

Dr. J. J. Ross, who was Premier of the Province of Quebec from 1884 to 1887, died in Montreal recently at the age of sixty-eight years. He was appointed to the Canadian senate in 1887, and in 1891 became speaker of that body, a position he held until 1896, when he joined the administration of Sir Charles Tupper, which was defeated a few months later. He was a graduate in medicine of McGill University.

Dr. David H. Bartine died at Merchantville, N. J., on May 3d, at the age of sixty years. He was graduated from the medical department of the University of Pennsylvania in 1862, and in the same year entered the army as assistant surgeon of the 114th regiment Pennsylvania volunteers. Subsequently he was assigned to General Meade's headquarters as surgeon and promoted to the rank of major. He was honorably discharged in 1866 and took up his residence at Merchantville.

Dr. M. Albert Rhoads died at Reading, Pa., on May 4th, at the age of fifty-three years. He was secretary of the Reading Society of Natural Sciences, ex-president of the Reading board of health, at one time a pension examiner, and for twenty-five years chief of staff of St. Joseph's Hospital.

Dr. Percy M. Graham died at Philadelphia on April 23d, at the age of forty years. He was graduated from Jefferson Medical College in 1888, but soon thereafter symptoms of meningitis following a blow upon the head in earlier life by a base-ball bat developed and eventuated in blindness, and this together with general ill-health cut short his career.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

VITAL STATISTICS—BIRMINGHAM CONSULTING SCHEME—HOSPITAL MANAGEMENT; EXAMPLES, NATIONAL, OPHTHALMIC, ORTHOPÆDIC—PRINCE'S FUND—LETTSOMIAN LECTURES—MILROY LECTURES.

London, April 19, 1901.

The sixty-second annual report of the registrar-general has just been issued. It gives the various statistics for the year 1899. If this seem a little late you will remember that quarterly returns have been published in the mean time, and that the mass of figures requires time for setting forth in due order. The population on which the various rates are reckoned is of course only an estimate—so far as concerns the changes that have taken place since the last census. The figures of the census just taken will in due time be available for our vital statistics. Meantime I may note a few as to the year 1899. The marriage rate was higher than in any year since 1876. This rate has been increasing each year from 1895. The birth rate has, however, fallen instead of rising—a fact which many regard as ominous. The previous year was the lowest recorded since the registration system began, in 1837. Now the record has been passed by a slight additional decrease. The deaths are calculated to be at the rate of 18.3 per 1,000—not far off the average for the decade, which was 18.4.

The promoters of the Birmingham Consultative Institute seem determined to carry out their scheme. Dr. Irvine's resignation, which they declared would not be proffered, has been sent in as I reported, and advertisements are now issued for a physician and surgeon to carry on the plan. The committee have come to the conclusion that there is no hope of an agreement with the profession—so I read in the local papers. Mr. Arthur Chamberlain and his few supporters continue to tilt against the Birmingham doctors, but without effect. These gentlemen have been insulted by the supporters of the Institute, and cannot see why they should provide charity for Mr. Chamberlain's workmen. Let them only hold together and ostracise any man who accepts office at the Institute. Then his doing so may bring him before the Medical Council, notwithstanding Mr. Chamberlain's threat to seek legal interference.

The editor of *The Nineteenth Century and After* has admitted an article by Mr. Burford Rawlings, the "secretary-director" of the National Hospital for the Paralyzed and Epileptic. The anger of Mr. Rawlings at his defeat is obvious throughout his labored attempt to show that the medical officers of hospitals ought not to be represented on the managing boards. He does not cite the National as a case in point or go into his own quarrel on the question, but tries to convince the reader that doctors are only servants of the committee and must be denied a voice in the management. To be honest he should have added that secretaries, being paid servants, should manage everything—for that is the crux of the whole matter. He is obliged to admit that doctors are a necessity to a hospital, but says the medical mind is arbitrary "to a degree undreamed of by the uninformed." I suppose he considers himself well informed and capable of instructing the world on the matter. But he may find that the world will not take him at his own valuation, and even the apathetic subscribers to the National will prefer the service of a staff that cannot be matched to a secretary who does not see that he is the subordinate. He sneers at the honorary staff as servants—what is he whose services are by no means honorary?

There are other hospital troubles besides this. I mentioned formerly how Moorfields, the Mecca of ophthalmologists, had sold its renowned building and erected another. The result is an enormous debt, and, as I stated, an increase in the annual rent and taxes which is crippling the charity. Truly, medical managers could not have done worse than this non-medical board.

Another case is that of the Royal Orthopædic Hospital. There has been some discussion about this for two years or more. One committee was dismissed, as it was alleged to be about to sell the site for less than its value. Those who prevented this folly are now alleged to have acted just as absurdly. They have spent about a couple of thousand pounds on repairs, and now, it is said, have offered to take less than the valuation by some £7,000 or more. Surely a lot of doctors would not be more unbusinesslike.

At one time the Prince of Wales' Hospital Fund recommended the sale of the site, but I hear that this unfortunate step has been rescinded. It was quite outside the duty of that fund and caused many misgivings as to its management. The present deadlock seems to be largely due to the change of mind of the chairman, who seems desirous of imposing his will on the hospital. As he is no authority on hospital matters, he would be wiser to follow the example of the Fund and withdraw from a false position.

Mentioning the Prince's Fund reminds me that its name will be retained; the King becomes its patron and the Duke of Cornwall and York succeeds His Majesty as president.

Senile changes must always be of interest to every practitioner, so that Dr. Mitchell Bruce had a good subject for his Lettsomian lectures at the Medical Society, where he discoursed on the affections of the heart and arteries in middle life and advanced age. He dealt in a practical manner with such disorders of the circulatory system as are most apt to occur after about forty years of age, and he brought to bear on the subject a considerable amount of clinical experience. There was indeed a good deal of the clinical lecture about the three discourses, with their successive discussions of the etiology, pathology, diagnosis, prognosis, and treatment. On all these points, however, Dr. Bruce had facts to state and their applications to consider, and few men could have listened to the course without instruction or at any rate without gaining some useful suggestions. He reminded his audience that with advancing life vascular changes normally occur which are not pathological and should not be hastily put down as degeneration. And yet these changes may render other influences more potent for injury and render it desirable for the individual to take more care of himself. Physical and nervous strain, disturbances of metabolism, and predisposition to certain diseases are to be reckoned with. The dietary may require to be readjusted to the changed demands of the system. Exercise should have careful consideration

in relation to the past and present clinical history, and those diseases which usually occur at the late period of life should not be forgotten as likely to show early manifestations. Very often, when cardiac disturbances are complained of, there is no evidence of pathological change, and we must look for the exciting cause outside the circulatory system. Even in senile heart, or in chronic valvular disease, the patient's trouble for which relief is sought often depends on the addition to the morbid change, of indigestion, worry, catarrh, improper food, violent exertion, or indulgence in alcohol, tobacco, or some other article of diet which disagrees. Moreover, in younger men with some degree of cardiac mischief it is not uncommon for the symptoms to be out of all proportion to the physical signs, and for the explanation to be found in such causes and relief to follow their removal.

With regard to alcohol and tobacco, Dr. Bruce had some excellent advice to give. As to the latter we seldom have to do more than confirm the patient's suspicions and recommend temporary abstinence. With the former it is different. "Alcoholism grows by what it feeds on, and our best efforts are often vain." This phrase of Dr. Bruce's well sums up much experience, and the terrible fact fully justifies his suggestion that we should exercise more fully than heretofore our personal influence to discourage habitual drinking. Many persons will pay more attention to the dangers described by their physician than to abstract or moral arguments. They are more likely to be frightened than persuaded to sobriety.

In connection with Dr. Bruce's observations on alcohol I may mention a speech made at the Temperance Hospital the other day by the Archbishop of Canterbury. His Grace has for many years been one of the most prominent teetotallers in the kingdom, and has consistently advocated the abstinence from alcohol which he practises. At a hospital it was natural to mention the position of patient and doctor in this respect. He said that if under a trusted adviser he was ordered alcohol as a medicine he did not go so far as to say he would refuse it. If he could not trust his physician, he would go to another; but the profession now does not say health cannot be restored without alcohol, and does not object to total abstinence. Most people will be ready to acknowledge that the Primate is right. Alcohol as a medicine has no more to do with its habitual consumption as a beverage than chloroform, ether, or other drug. Only on account of its insidious effects as described by Dr. Bruce the doctor who prescribes it should do so in definite doses, and best perhaps in mixtures.

The Milroy Lectures at the College of Physicians were this year delivered by Dr. John F. J. Sykes, lecturer on public health at Guy's Hospital. He devoted them to the influence of the dwelling upon health in relation to the changing style of habitation. Thus, the "housing question," which has demanded attention from sociologists and forced its way into politics, was treated in its many phases from the point of view of the adviser on public health, especially as regards great cities like London. A distinction was made between the pressure of urban population, which compresses the requirements of dwellings into the smallest limits, and the dilapidation of dwellings and general deterioration of localities which bring about insanitary areas. The relief of the pressure is to be met by improved means of transport between centres and suburbs; building more dwellings; attracting to outlying districts, etc. The remedy for dilapidation and deterioration is to be looked for, Dr. Sykes considers, in the reconstruction of the worst areas in healthy flats and the adaptation of better streets and houses of the unhealthy "floor type" to a healthy "flat form," together with improved sanitary laws and by-laws, taking the dwelling as the basic unit.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE TREATMENT OF SYPHILIS—OFFICIAL EXAMINATION OF ACCIDENT CASES—SODIUM SALICYLATE IN EXOPHTHALMIC GOITRE—MOSQUITOS IN PARIS—TREATMENT OF INTESTINAL HEMORRHAGE IN TYPHOID FEVER—SPINAL COCAINIZATION.

PARIS, April 16, 1901.

THE Paris school of dermatology, as opposed to the Vienna school, has no better representative of its principles and practice than Dr. Brocq, physician of the Broca Hospital. Dr. Brocq is perfectly willing to admit the parasitic origin of certain forms of eczema; he is continually mentioning in his clinical lectures the opinions of different members of the Vienna school, but he upholds to a great extent the traditions of the French school, and, though a relatively young man, he does not allow himself to be carried away by any new wind of doctrine or to grow too enthusiastic over any novel method of treatment.

A good example of this is furnished by a recent article he has published in the *Presse Médicale*, in which he shows how he habitually employs mercury in the treatment of syphilis. It has become a common practice to use subcutaneous injections of mercurial compounds, whether they be insoluble, like calomel, or soluble, like biniodide or benzoate or other compounds. The administration by means of pills or draughts has almost completely fallen into disfavor, and yet, according to Dr. Brocq, there are certain advantages attached to this method.

To examine the defects offered by the latter, one should admit that pills do not always dissolve readily, that their action is therefore uncertain, and that, moreover, they may exert a pernicious influence on the mucous membrane of the intestine. Dr. Brocq is a staunch believer in the principle, which most French physicians adhere to, that it is always infinitely better to give drugs in a liquid form, as one is much more sure of their producing their entire effect. Of course given at one dose any soluble salt of mercury may cause colic, so Dr. Brocq has made it a practice with a great many of his patients to give the quantity administered daily in small doses, about four to six doses being given. The advantages offered by this mode of treatment are that the dose given is accurately gauged, the patient is not obliged to visit the physician to submit to the injections, and he does not run any risk of having abscesses or pains caused by the injection. Dr. Brocq has found that giving mercury in small doses four to six times daily proves to be much more efficacious, and it is only when he was treating certain forms of psoriasiform syphilides of the hands and feet that he has experienced failure. In such cases the best procedure is to use immediately injections of calomel. Van Swieten's solution is the preparation used by Dr. Brocq, and he recommends taking it in milk. In case of colic paregoric would be the best preparation to relieve the pain. Some two thousand patients have been treated in this manner at the Broca Hospital during the last three years and a half, and with the best results.

The chamber of deputies passed a law recently which has excited a good deal of comment, not only among laymen, but also among the members of the medical profession. It is a measure providing for the indemnity that is to be given to a workman by his employer in case of accident, and there is one aspect of the working-out of the regulations connected therewith which is of considerable interest to the ordinary practitioner. A medical certificate must be made out as soon as possible after the accident, and it is supposed to be the physician of the insurance company who is obliged to examine the patient. In case the latter has been already examined and treated by another physician immediately after the accident, it would seem to be a moot question whether the second physician has a right to undo the bandages or remove the apparatus that the first has already applied. In an article by the editor of the *Presse Médicale*, Dr. de Lavarenne, various cases are brought up, and it would seem to be better for the physician of the insurance company to trust to the judgment and opinion of his colleague and not make out his report without consulting him. In this manner the patient is not disturbed by the changing of his apparatus, and the physician cannot be accused of having caused any harm to his patient.

Dr. Babinski, the well-known neurologist of the Salpêtrière, has been treating some of his patients suffering from exophthalmic goitre with salicylate of sodium, and he is rather satisfied with the results he has obtained. One young woman, aged twenty-eight years, had begun showing the symptoms of this disease in 1898, and in January of 1899 all the important symptoms were clearly defined: goitre with pulsations, pulse at 140, tremulousness of the arms, bilateral exophthalmia, and loss of flesh. Salicylate of sodium was given, and ten months afterward there was complete transformation. The cure has persisted since.

A man aged forty-one years had the different symptoms of Graves' disease with the exception of the goitre. The pulse was 120 a minute. After having taken salicylate of sodium for a month the pulse had gone down very noticeably. The patient did not continue the treatment steadily, but there was much improvement when he was last seen. In a third case, in which the only symptom was a goitre, the use of salicylate of sodium removed it in less than two months.

Last year, during the Exhibition, much complaint was made about the mosquitos, which were much more numerous than usual. It might be asked if the influx of visitors did not have something to do with it. There was at that time some question as to their effect on the general health of the community, and the question was taken up again at a recent meeting of the Academy of Medicine, and Professor Debove spoke of the means that might be used to suppress them. A number of public parks in Paris are furnished with small ponds where the water remains stagnant, and Dr. Debove said that in case the city could not afford to have running water in such places an easy means

of suppressing the larvæ of mosquitos was to pour kerosene on the water every now and then.

Dr. Mathieu described recently at the Society of Therapeutics the treatment he uses in case of intestinal hemorrhage in typhoid fever. It consists in suppressing the baths and replacing them by the cold pack so as to move the patient as little as possible, giving small doses of opium to quiet the intestine, reducing the quantity of ingesta to a minimum, and lastly administering an enema of from one to one and one-fourth quarts every morning at a temperature of 115° F., containing about one drachm of chloride of calcium. Fifteen to forty-five grains may be given by the mouth. Mathieu does not believe in giving more than this, as the coagulability of the blood is diminished by giving too large doses. In eight cases in which Mathieu employed this method the results were quite satisfactory.

Intrarachidian injections of cocaine are as much talked about as ever, and the discussion is waxing fiercer and fiercer between Dr. Tuffier and his partisans on the one hand and Professor Reclus on the other. Professor Reclus, who is looked upon not only in France but also in Germany as an ardent advocate and propagator of the use of cocaine, does not favor the new method, and he has spoken quite severely against it at the Academy of Medicine. He said he considered it would be advisable to wait until the question had been more thoroughly examined before applying it indiscriminately, and he sent to the *Presse Médicale* a letter written to him by Bier in which the latter speaks disparagingly of the methods used with so much enthusiasm. He also speaks of the trial he made of it on himself, and advised the promoters of the method to do likewise before using it on others. Dr. Tuffier sent a reply to the same paper, in which he took up the German physician's statements and ardently defended his own process, declaring that it was not necessary to wait until the opening of the German Medical Congress on April 11th to be told what constituted a safe method for performing these injections.

THE URIC-ACID PROBLEM.

An Open Letter to Alexander Haig, M.A., M.D. Oxon., F.R.C.P.

My Dear Doctor: I have read your work entitled "Uric Acid as a Factor in the Causation of Disease," also your recent article on "The Causation, Prevention, and Treatment of Gout" (Medical Record, January 26, 1901), and have just finished the perusal of your "Diet and Food," third edition, Philadelphia, 1901.

The subject of which you treat is of unquestioned importance, but the propositions you defend are in many instances so extraordinary and so contrary to my experience of over thirty-five years as a practitioner, and so different from the teachings of others, that I must beg your indulgence if I seek a little more light on some points that appear to be slightly obscure. Possibly my failure fully to understand you is due to my lack of familiarity with the English language, which I am aware differs in many respects from the American, the language of my birth and of my education, such as it is. Possibly an English dictionary would have helped me, but unfortunately the only dictionaries at my command are American; namely, the "Century," the "Standard," and "Foster's Medical," which I hasten to assure you are held in high repute in this country.

On page 2 of your "Diet and Food" you say: "To substitute a certain amount of scientific precision for the rule of thumb methods is the object of this little book." By this, then, you should be judged.

On page 6 you say: "Most physiologists have agreed that good strength and nutrition in adult life can be maintained on about 3½ grains of urea per pound of body weight per day." I question very much if any physiologists will agree with that statement. I am an adult and weigh about two hundred pounds, but I must certainly decline to make any attempt to maintain my "strength and nutrition" on 700 grains of urea per day.

On page 57 you say: "We have already seen in Chapter I. that the body weight in pounds, multiplied by 9, gives the minimum amount of albumens required for a sedentary life, and by 10 or 10.5 those required for an active life, such as that of an out-door labourer." Taking again my body weight at two hundred pounds, must I ingest eighteen hundred pounds of "albumens" per day, or over what period must this allowance be spread? Tell me, further, where I am to obtain these "albumens." This word, which you may possibly use as a plural form of albumen, is not to be found in either of the dictionaries above referred to. Albumen, however, is defined as "the white of an egg; 2, the nutritive material that fills the space in a seed between the embryo and the seed-coats" (Standard). "The white of an egg; also formerly applied to the principle contained in the white of an egg or albumin (*q.v.*)" (Foster). Pursuing our search we find albumin defined as "the transparent viscous nitrogenous substance ($C_{72}H_{112}N_{18}SO_{22}$) which forms the chief and characteristic constituent of the white of an egg. Albumin is also found in the blood and in all serous fluids, also in many animal and vegetable juices and solids" (Standard). Foster defines substantially as above, and adds, "In its chemical behavior albumin is a weak acid, apparently dibasic (or perhaps tetrabasic), forming both acid and neutral salts (albuminates) with bases."

Albumen: "The white of an egg; an animal or vegetable principle which occurs in the purest natural form in the white of an egg; in the latter sense more correctly called albumin. The white of egg (albumen) contains about fourteen per cent. of albumin. The blood of five oxen yields about two pounds of albumin" (Century Dictionary).

In view of the foregoing I can hardly believe, dear doctor, that you intend to recommend a daily diet of 3½ grains of urea per pound of body weight with a view to maintaining "good strength and nutrition." It would be a little monotonous, to say the least; as would also be the diet of nine times the body weight of "albumens" (whether white of eggs or albumen from plants) to be consumed within a period not definitely stated.

On page 8 you say, "The albumen in 2¼ pints of milk = 590 grains." The composition of milk varies within very wide limits, but so far as I am aware the milk of American cows does not contain any "albumen," though it does contain a minute quantity, say about three-tenths of one per cent., of albumin, a rather negligible quantity from a dietetic standpoint, but it does contain a very considerable quantity of casein, say twenty-five or thirty per cent. of the total solids. Why, may I ask, do you apparently overlook this exceedingly nutritious substance? Can it be possible that you regard albumen and casein as identical? They certainly cannot be, unless my American dictionary is at fault. Casein is defined as "the chief nitrogenous ingredient of milk. It does not coagulate spontaneously like fibrin, nor by heat like albumin, but by the action of acids and rennet. It is closely allied to, if not identical with, legumin" (Century Dictionary). Does it not occur to you that in speaking of albumen and "albumens" you have been using these terms in a very loose manner, and not in accord with the "scientific precision" that you claim to be the keynote of your book? Would it not have been better to substitute the word albuminoids for the word "albumens," and still better employ the expression proteids, and thus bring yourself more in line with the results of modern scientific investigations?

Turning from this, which I trust you will not consider a frivolous play on words, to some of your theoretical propositions, I find the following (page 28): "The first requisite for strength and power of endurance is a satisfactory and sufficient supply of albumens" (proteids?); (page 29) "Force is thus in all directions proportional to urea, whether gauged from hour to hour or from day to day." These passages, and others in your book, would indicate that in your opinion the maintenance of energy, that is, power to do work, is to be secured mainly by the ingestion of "albumens," or, more properly speaking, by the use of a diet consisting of organic compounds that contain nitrogen (proteids) in contradistinction to those that do not contain this element, to wit, the carbohydrates and hydrocarbons. On this point I must certainly join issue with you. By general consent of physicists and other scientific investigators, energy, force, power to do work, or whatever you may choose to call it is measurable in terms of heat, the accepted unit of which is in the calory (the heat required to raise one kilogram of water one degree centigrade).

If we liken the body to a machine, a steam engine, for instance, we find that the latter is a structure of iron, steel, brass, etc., put together so as to enable it to perform certain functions when the requisite energy is supplied from without. If any part becomes worn or broken, new metal is used to replace it. So the body is a structure composed of bone, muscle, tendon, etc., and certain secondary organs, heart, lungs, liver, kidneys, etc. This structure with its several organs is during life subject to constant wear and requires renewal of parts. This renewal is not, however, as in an engine, accomplished by the replacement of gross parts, but rather by constant substitutional changes of an almost infinitesimal character. The new material required to replace the old is introduced as food, and consists in the main of proteids (carbon, hydrogen, oxygen, nitrogen) and in but slight degree of combinations consisting of carbon, hydrogen, and oxygen alone. As steel is the backbone, so to speak, of the engine, so nitrogen is that of the (soft) tissues.

If, now, we desire to utilize the engine, we must arrange for the development of energy by supplying fuel and heat (carbon and hydrogen), whose oxidation develops heat measured in calories. In like manner the development of

energy in the body is brought about by the combustion, that is, oxidation, of these two elements supplied as food in carbohydrates (starches) and hydrocarbons (fats), and to a less extent in proteids, which contain the C and H supplemented by N.

Should you desire any further evidence that energy is to be measured in terms of carbon and hydrogen, rather than in terms of "albumens" kindly consult "A Digest of Metabolism Experiments," by Professor Atwater and Dr. Langworthy, published by the United States Department of Agriculture.

Despite your statement that energy is mainly derived from the "albumens" you say, page 37:

"Hence the records we are now getting from all sides show that the less animal flesh people take the better do they come out in trials of force production, and especially in endurance. . . . Now, so far as I know, the vegetarians of this country are pretty decidedly superior in endurance to those who feed on animal tissues." Surely in the ordinary vegetarian dietary there is less "albumens" than in the daily food of the meat eater. How, then, do you reconcile your two apparently conflicting statements, especially in view of the fact that you would exclude leguminous seeds, peas, beans, lentils, termed by you "pulses," which are well known to contain a notable quantity of nitrogen?[1]

On several pages of your books you speak of "the xanthins," but what they are, or how many of them there are, you do not say. Turning to the Standard Dictionary I find xanthin to be "a gaseous decomposition product of certain xanthates, probably carbon disulphid," also "the insoluble yellow coloring matter contained in flowers;" also "a white crystallizable compound ($C_5H_4N_4O_2$) contained in blood, urine, and other animal secretions." You need not remind me that there is a substance named heteroxanthin, another paraxanthin, and still another hypoxanthin, as none of these is xanthin, and collectively should not be called "xanthins." Call them leucomains, if you will, or preferably katabolic products, and we will then be one step nearer to an understanding of your writings, and possibly also a step nearer to a solution of the uric-acid problem. These are all the xanthins that I can get on the track of. If you know of any more xanthins, kindly define them with sufficient precision to enable them to be identified, as I desire in a later letter to go into this matter a little more fully.

Henry G. Piffard, A.B., A.M., M.D., LL.D.; *Professor (Emeritus) New York University.*

THE USE OF "THE HOT-BED" IN KOREA IN THE RECOVERY ROOM AND FOR TREATMENT OF SURGICAL AND OTHER SHOCK, AND SIMILAR CONDITIONS.

To the Editor of the Medical Record.

Pyengyang, Korea.

Sir: There are not many things out here in Asia which, as a means of securing human happiness and comfort, we find superior to what "modern civilization" has produced or perfected, but we occasionally come across something which we have to admit is an improvement on anything we have so far made. The method of heating houses in Korea consists of making flues under thin stones which are covered with clay mud, and over that either mats or oil paper. The fire heats the floor, and less fuel, which consists of brushwood, millet stalks, dried grass, etc., is used than at first thought would seem necessary. This calorific arrangement is not to be commended as a fine thing to those in health, though as a matter of fact it has far fewer objections to those who have closely observed its effects than those who merely "travel through," and look on it as a "roasting process," would have their readers believe.

But the benefits I have obtained from it after severe surgical operations, and the beautiful reaction got in other conditions of shock or temporarily lowered vitality, in giving an even heat to the entire body, are what prompt me to make this report of it. It is true, of course, that it is the practice of certain surgeons in St. Louis, and perhaps elsewhere (I have not been in America since 1895), to have hot-water or steam-heated operating-tables, and I have read the good reports of the benefits they derive from it. The prompt reactions and quick recoveries I have had in cases like thigh amputations are the special reasons I write this, and I feel sure that if the "recovery room" in hospitals was provided with a hot-bed, it would soon yield such good and marked results that once instituted it would thereafter be deemed a necessity.

I could recite many instances in which most marked effects have followed the hot-bed, and they are not confined to surgical cases. Of the latter, however, a distinct one comes to mind. A man aged sixty-five or seventy years after an amputation of his arm had the misfortune to let the ligature around the main artery slip (the doctor tied it all right, of course!), and before it was discovered he lost considerable blood. Saline solution was injected, but it seemed to me that the recovery from the quite considerable shock which resulted was due as much to the hot floor as to the saline solution. Both together certainly tided over a very serious condition.

The heat from a hot-bed, ranging evenly as it does all along the backbone, secures a quietness to the nervous system, which I believe prevents the vomiting after anæsthetics, almost unknown with me. It tones up the blood, warming the big arteries, and in all ways secures those conditions, mentally and physically, so much desired after surgical work and which those who witness them best describe as "happy."

I commend the hot-bed, made as suggested by the skill and genius of those whose business it is to provide surgical appliances, to secure prompt reaction, and consequently shortened recovery after surgical operations and for all conditions in which the cumbersome, inconvenient, and often ineffective "hot-water bottles" and bags have heretofore been applied. Typhoid fever is one condition in which I think I have seen excellent benefits from the hot-bed; but of that more when I have more cases to report.

J. Hunter Wells.

[1] Since the foregoing was written I find (*Philadelphia Medical Journal*, March 30, 1901) the following by Benedict: "Most exhaustive experiments (see Gamgee and other authorities) have shown that muscular exercise does not actually destroy much albumin, either of the muscles themselves, or of the circulating plasma. Exercise, and, in fact, all bodily work involves a comparatively slight wear and tear of tissue, and an enormous (relative) combustion of carbohydrates and fats to produce needed energy."

WOUNDS OF THE HEART.

To the Editor of the Medical Record.

Sir: My attention has been called to an article in your journal of December 15, 1900, by Dr. L. L. Hill, of Montgomery, Ala., on "Wounds of the Heart." Dr. Hill had evidently not seen my article in the *Annals of Surgery*, February, 1895, in which I reported "A case of stab-wound of the pericardium, terminating in recovery after resection of a rib and suture of the pericardium." My operation was done in September, 1891, while I was in charge of the St. Louis City Hospital. Dr. Hill states that the first operation upon the heart was done in 1896 by Farrina and Cappelen. My operation upon the pericardium antedates this by five years.

H. C. Dalton, M.D.

St. Louis, Mo.

Progress of Medical Science.

Journal of the American Medical Ass'n, May 4, 1901.

A Case of Transient Motor Aphasia, Complete Anomia, Nearly Complete Agraphia and Word Blindness, Occurring in a Left-Handed Man; with Especial Reference to the Existence of a Naming Centre.—By C. S. Potts. The essential features of the case are suggested by the title. The patient was a man aged forty-two years, a coal miner, in previous good health. He suddenly became dizzy and weak on the left side, but power was not completely lost. There was no loss of consciousness, but he found that he was unable to talk, although he knew what he wanted to say. He also noticed that he was unable to write anything excepting his name and address. In the course of a day or two he regained the power of speech, excepting that he could name neither objects nor people. He says that he knew the name but could not express it. The muscular weakness of the left side improved rapidly, excepting the muscles of the face and tongue. The writer advances the following theory to account for the inability to name objects presented by this patient: that there is a naming centre, probably somewhere in the temporal lobe, possibly part of the superior temporal gyrus, and that a tract leading from this centre to the centre for the preservation of the motor memories of speech was damaged. Such a tract would likely run through the insula and thus would be in a location easily reached by a lesion that had, judging from the word blindness and motor paralysis present involved the angular gyrus and extended subcortically in a direction to impair the function of the fibres running from the centres for the lower part of the face and tongue to the internal capsule.

Ocean Climates; their Effects and the Cases they Benefit.—By J. A. Robison. The following are the peculiarities of ocean climates: (1) They are more equable on account of the temperature being tempered by ocean currents instead of by winds as on land. (2) They are warmer. (3) The air is more nearly aseptic, is free from dust, and

contains more ozone than land air except in the highest altitudes. (4) It contains more moisture than land air and the moisture is laden with the volatile elements of sea water. Sea air has a sedative effect on the nervous system, increases metabolism, weight, appetite, and inclination to sleep, and so to those with whom it agrees it is a sedative. Sea air is a specific for hay fever, whooping-cough, purulent and chronic bronchitis, and of benefit in incipient tuberculosis and in tuberculosis when cavities and empyema exist. Asthma is frequently benefited, scrofulous affections are frequently cured, debility is often removed, and chorea is frequently benefited. The patients helped most are the overworked and melancholics, the brain-goaded sufferers, the women who are harassed by domestic cares or society dissipations, the children who are nervous and weakly, and, in short, the army of neurasthenics. In this class of cases it is a question whether the improvement almost invariably following an ocean voyage is due so much to the change of climate as to the change of scene and entire change of life.

Adhesive Rubber Dam for the Prevention of Possible Infection at the Site of Operation.—By J. B. Murphy. The mode of application of the plaster is thus described: The field of operation is prepared in the usual way. It is then thoroughly dried, washed with ether, and the rubber applied, the latter being put slightly on the stretch as it is brought in contact with the skin. The small quantity of ether retained by the skin increases the adhesive power of the dam. After it is applied, it is washed with alcohol or with any other sterilizing solution. The incision is now made through the dam, simultaneously with that in the skin, and to the same extent, as it stretches even more readily than the latter and there is no trouble in retracting it. The dam remains in position until the sutures are inserted and tied, after which it is lifted at one end, put a little on the stretch, and divided at the points of suture in a manner similar to that of dentists in removing the dam from teeth. Its second practical application is in all suppurating and draining wounds. In these cases it should be left on until suppuration and discharge have ceased, so that it may protect the skin and prevent the erosion and eczema which are so frequently caused by the irritation of a purulent discharge. For this purpose it is particularly applicable in cases of artificial anus, cholecystostomy, gastrostomy, nephrotomy, suprapubic cystotomy, and a draining, suppurative, circumscribed, or general peritonitis.

Absolute Increase of Measurement from the Anterior Superior Spine to the Malleolus as a Sign of Hysteric Hip Disease.—By J. J. Putnam. The writer calls attention to the fact that sometimes the differential diagnosis between tuberculous and hysterical disease is exceedingly difficult. The shortening of the measurement between the anatomical points named in the title is a matter of common knowledge, but it is not so well known that a lengthening between the same two points occurs in hysteria. Lengthening may also occur in the early stages of tuberculous disease when pain induces the muscular contraction which leads to the tilting of the pelvis when no erosion of the joint has yet taken place. In hysteria, on the other hand, the lengthening comes on with the contracture and does not pass away, no matter how long the morbid conditions may last. An illustrative case is given in detail.

Limitations of the Laryngologist in the General Treatment of Nose and Throat Diseases.—By H. W. Loeb. The writer enumerates the general systemic conditions which may complicate nose and throat affections, and ventures the following as the limitations of the laryngologist's efforts under the conditions stated: (1) Acute conditions of the nose and throat, influenced by remedies which have an immediate local effect. (2) Rheumatic nose and throat conditions which exhibit a positive and early relief under appropriate treatment. (3) Syphilis of the nose and throat in which general treatment may be best observed by watching its effect upon the local lesion, and in which the local process is rapidly destructive. Even under these conditions, the patient's chances might be improved by assistance from one whose attention is less directed to localism.

A New Operative Method to Expose the Seminal Vesicles and Prostate for Purposes of Extirpation and Drainage; a Preliminary Report.—By Eugene Fuller.

Myasthenia Gravis Pseudoparalytica (Asthenic Bulbar Paralysis).—By J. T. Buist and E. G. Wood.

The Gyromele in the Diagnosis of Stomach and Intestinal Diseases.—By F. B. Turck.

The Classical Cæsarean versus Porro Cæsarean.—By G. M. Boyd.

The Present Status of Spinal Surgery.—By Samuel Lloyd.

The Pharmacology of the Nitro-Sugars.—By C. R. Marshall.

Medical News, May 4, 1901.

A Report of Twenty-Four Operations Performed during Spinal Analgesia.—William Seaman Bainbridge draws the following conclusions from fifty cases, among which are the twenty-four which he reports in this article: (1) Cocaine is far more satisfactory than eucaine. The latter is less potent, more evanescent; the areas of analgesia are frequently "patchy," having the pain sense retained all around them and not being so complete below definite levels. The cocaine produces no more unpleasant after-effects than eucaine, and is decidedly more reliable. (2) Analgesia to the level of the diaphragm can be depended upon in all cases in which a moderate dose of a potent solution of cocaine has been introduced by lumbar puncture. In some the analgesia is sufficient for operation on the upper extremities. (3) Complete analgesia, including the eyes, mouth, and throat, has occurred. It does not entail more severe after-effects than when the lower extremities only are involved. (4) The preparation of the patient as for a general anæsthetic diminishes all the unpleasant effects of cocaine and eucaine, and often prevents them altogether. (5) By moderate doses of bromides before the injection the initial vomiting is frequently avoided and the liability of headache lessened. (6) In neurotic patients there are often hysterical symptoms directly following the completion of the injection, but, as a rule, in a few moments a calm follows and the patient lies perfectly still. (7) Initial nausea and vomiting often occur soon after the puncture, but last only for a moment or two, and usually do not recur during the operation. As consciousness, as well as the muscular power, is preserved, the danger of the introduction of the vomitus into the lungs is practically *nil*. (8) Analgesia lasts from thirty minutes to four hours. (9) Depression after the puncture is inconsiderable. The use of ethyl chloride (Bengue) largely prevents pain when the needle is introduced. (10) The preparation of the patient, the use of nitroglycerin by hypodermic injection, or the employment of coal-tar products with caffeine, control the headache, which is in many instances an after-effect of spinal puncture. (11) In a few cases there may be motor paraplegia or vertigo. Both are temporary. (12) Spinal puncture has not affected normal or diseased kidneys. (13) Usually the tactile power, muscular sense, and the ability to detect heat and cold are retained. The cautery at a dull-red heat causes no pain, while hot water produces marked discomfort. (14) Usually the patient sleeps the first night. (15) There is often a rise of temperature of a few degrees within eight or ten hours of the operation. Whether this is the direct result of the puncture or the effect of psychic disturbances is not determined. The circulation and respiration are not seriously embarrassed.

Some Sources of Error in Laboratory Clinical Diagnosis.—Theodore C. Janeway declares that only the clinician is in a position to balance all the facts in a given case and to determine their relation to one another. The diagnostician's first requisite is not technical skill but a judicial mind capable of weighing the value of evidence. The sources of possible error in the application of laboratory methods to diagnosis are twofold: those due to the methods themselves or faulty technique in their use, and those due to inaccurate reasoning from accurate results. In the examination of urine the most conspicuous technical error is a failure to filter the urine. The presence of albumin in the urine is not normal, but no conclusions can be drawn from it, and a further investigation by other methods must be instituted to determine its source. The microscope gives the most evidence on this point, but the whole examination furnishes subsidiary information. Moreover, the absence of albumin at one or even repeated examinations does not at all preclude the existence of kidney disease. In Fehling's test for sugar the value lies only in its negative evidence. A reduction merely indicates the necessity for applying further tests. The tests which do give positive indications of the presence of sugar are the polariscope, fermentation, and the phenylhydrazin reaction. The persistence of sugar in the urine does not constitute diabetes; only its persistence after the reduction of the carbohydrates in the diet to a small amount can warrant that diagnosis. A representative specimen of urine for any examination should consist of the mixed urines passed on at least three different occasions during at least twelve hours. The only common source of error in the use of the urinometer is a neglect to make the correction necessary for changes in temperature. It should not be concluded that a urine does not contain sugar if it is below some arbitrary point. Another error in diagnosis is to mistake glycosuria for diabetes. A few casts may be thought to indicate renal disease, whereas the more important lesion may be in the pelvis of the kidney or bladder as shown by the presence of blood or pus cells. It requires a trained microscopist to examine the blood. In any test which requires the matching of shades of color, the error may be considerable and varies with the personal equation. The

most common errors are in connection with the study of the malarial organism. In staining for the tubercle bacillus in the sputum the most frequent faults are insufficient staining and incomplete decolorization. The most that can be obtained by analysis of gastric contents is a functional diagnosis. The most critical examination of the physical and psychical condition of the patient can alone guard against serious errors in diagnosis of stomach disorders.

Philadelphia Medical Journal, May 4, 1901.

Localization of Sound and its Bearing on Hearing, Especially in Unilateral Deafness.—B. Alex. Randall speaks of the attempt which has been made to map the field of hearing in a manner analogous to that of vision, and calls attention to the essential difference—that sound-waves are not, like light-waves, propagated only in straight lines. The absolute field of hearing is hardly definable. When both ears are good, there should be little difficulty in localizing many, at least, of the sounds that come to us. Not only are they lateralized, but the other factors as to the indirection can generally be subconsciously determined. This is a matter of differential impression and analysis, for which an appreciable time is requisite. One ear is often given to the sounds which interest us, while the other merely keeps guard-hearing. When one ear has to act alone, the condition is very different. The physical problem is little changed, but the psychic task is far more complex. One side of the brain, to a much greater extent than usual, has to receive and analyze all the impressions, and these lack that element of double, yet diverse, character which in vision we call stereoscopic. Rotation and other movements of the head can, as in binocular vision, furnish some localizing factors; yet the problem remains too largely a mental one, and the "fatigue of the deaf" is by no means absent in those who, with one perfectly good ear, are often unrecognized by their companions as having any lack. It is time for the importance of "binaural hearing" to be more fully recognized, and for care to be taken to retain or secure it in those who are suffering for the lack of it.

Deaths from Anæsthetics.—D. H. Galloway states that three deaths from anæsthetics have occurred recently in Chicago, all within a period of ten days. The majority of surgeons seem perfectly willing that medical students or recent graduates without skill or instruction should administer anæsthetics to their patients. The ideal anæsthesia should be one in which the patient should have enough anæsthetic to allow the operation to proceed without his consciousness or interference with the surgeon's work, all this with the use of the smallest possible amount of the anæsthetic and not one drop more. Many operations are practically devoid of danger, but no anæsthetic is ever administered without jeopardizing the life of the patient. Students should be carefully instructed in the subject of anæsthetics, and be made to realize its responsibilities. The number of times a man has administered anæsthetics is no criterion of his skill.

Observations on the Use of Antistreptococcus Serum in the Treatment of Puerperal Sepsis, with a Report of Five Cases.—Frank A. Higgins, from his experience, comes to the conclusion that serum treatment has no place in the routine treatment of puerperal sepsis, that it should be used only in desperate cases after failure to obtain improvement by other and usually more efficient methods, and that if no improvement is shown after use for two or at most three days, and the injection of 40 to 50 c.c., it should be discontinued. He believes that its use is not free from danger; that it usually lowers the pulse and temperature, but at the same time has a correspondingly depressing effect upon the patient, and that it has not apparently lowered the mortality of the disease.

Exophthalmic Goitre and Fright.—E. W. Taylor reports three cases in which there was the association of a definite violent emotional disturbance with symptoms of exophthalmic goitre which came on immediately subsequently. The fact of mere coincidence, he says, is of course never to be dogmatically denied, but it is no straining of a point to maintain the decided probability of cause and effect. Some unknown predisposition, as in all other diseases, must be assumed; but the exciting cause may be regarded as the fright.

Contusions of the Abdomen.—By Charles L. Scudder.

New York Medical Journal, May 4, 1901.

Abdominal Pain in Typhoid Fever.—From an analysis of five hundred cases treated in Dr. Osler's service at the Johns Hopkins Hospital, J. McCrae draws the following conclusions: (1) About two-fifths of the patients are free from pain or tenderness, rather less than one-fifth have tenderness only, and pain is present at some time in about two-fifths of the cases, but during the course only in about one-third. (2) Pain due to some condition other than the specific bowel lesions was present in about fourteen per cent. of all cases, and in about two-fifths of the patients having pain during the course. (3) Pain occurred with hemorrhage or perforation in about five per cent. of all cases, and in about fifteen per cent. of the cases in which there was pain during the course. (4) Pain was most constantly present with perforation, when it was usually sudden in onset, severe in character, and paroxysmal in occurrence. The pain of perforation was most closely simulated by that occurring in some cases of hemorrhage, that from phlebitis, and that of unknown origin. (5) In about two-fifths of all cases with pain during the course no cause could be found. Should this occur with other abdominal symptoms the condition may much resemble perforation.

Spinal Anæsthesia by Cataphoresis.—By J. Leonard Corning. The author has devised an apparatus whereby it is possible to inject cocaine through the ligamenta subflava against the spinal dura, making the penetration of the anæsthetic through the latter by means of cataphoresis. He has tried the apparatus in one actual clinical case. Physiologically, the undertaking was successful, but practically he does not think it was, as a very long time was necessary for the induction of the anæsthesia, and the paraphernalia required were formidable. Yet subsequent endeavors along this line may yield more satisfactory results.

Some Remarks on the Cumulative Action of Digitalis, with an Illustrative Case.—Edwin Zugsmith believes from his experience in the following case that the symptoms of cumulative digitalis poisoning may be of grave omen. A female child aged twenty-three months had bronchopneumonia secondary to whooping-cough. The pulse becoming weak and irregular, a digitalis mixture was begun. Within a few days the temperature fell rapidly; the pulse fell to 60, and was somewhat irregular and hard. Nitroglycerin was given with a slight improvement. Compound jalap powder was then given and was followed by several watery movements, but this was apparently the only effect. Later morphine, then tincture of aconite, caused a little improvement in the pulse tension. At last the child's bed was drawn to the register, while a tent was constructed to cover the body and let in the heat, while the child's head was free. Almost at once the good effects were felt. The pulse improved, the mental faculties cleared, and the child began to drink considerable water. The hot-air bath was given at intervals at least a score of times, and always with the result of increasing the pulse rate and relieving the symptoms.

Vaginal False Membrane due to Bacterium Coli.—J. N. Hall reports this case of a healthy girl aged fourteen years. She began to complain of headache and general malaise, and the temperature was 101.8°. The case appeared like one of incipient typhoid fever. On the fifth day the temperature was higher, and on the sixth a false membrane was discovered by the mother. On the seventh day the temperature was 104° and the smarting and burning of the vagina continued. A dark patch, 2 cm. across, covered the inner surface of the right labium majus, a smaller one covering the opposing surface. An examination of a piece of the membrane showed a pure culture of bacillus coli. The urine contained neither albumin nor sugar. There was absence of colon bacilli. Under the application of a 1:5,000 bichloride solution the membrane was detached on the sixth day, the temperature became normal, and the girl has remained well ever since.

Reversed Pulsus Paradoxus due to Aneurism of the Aortic Arch.—By John Hay. Respiratory variations in the radial pulse, due to aneurism, are comparatively rare. In this particular instance the patient, a man aged thirty years, presented the interesting feature of a rhythmical variation in the right radial and right carotid pulses coincident with respiration, which was due to the innominate artery being compressed between the aneurism behind and the sternum and costal cartilages in front, the lumen of the artery being almost occluded toward the end of expiration. At the autopsy it was found that the aneurismal dilatation extended upward rather irregularly, one rounded projection having crept up and become tightly adherent to the anterior surface of the trachea. In the production of the dilatation it was chiefly the posterior portion of the aorta in the region of the transverse arch which had distended, the result being that the innominate and left carotid arteries, instead of arising from the convexity of the arch, as is usually the case, sprang from its anterior surface, and consequently as the sternum and bony thoracic wall descended with expiration these two arteries were caught and compressed between the thoracic wall in front and the aneurism behind. The result of this pressure on the left carotid artery had flattened it down on to the aneurism and had obliterated its lumen. When the patient leaned to the right his heart and aorta would be slightly displaced in that direction, and so the innominate artery was freed from compression. Thus was caused the increasing and decreasing obstruction in the innominate artery which gave rise to the rhythmical variation in the pulse. The aorta was much dilated as far as the lower border of the seventh dorsal vertebra, the bodies of the fifth, sixth, and seventh vertebræ being deeply eroded. The œsophagus was compressed by the dilated aorta. The valves of the heart were normal with the exception of the aortic cusps, which were somewhat fibroid and allowed of free regurgitation. The heart itself was considerably hypertrophied and dilated.

Tetanus Puerperalis.—By Kedarnath Das. The patient was a Hindu woman, who became infected in some way with the bacillus of tetanus and exhibited the characteristic tetanus symptoms, though finally recovering under the use of intra-uterine injections of bichloride, purgation, and sedative enemata. Intracellular injections of saline solution seemed to assist in the elimination of the toxins. The mortality in this affection is enormous, from eighty to ninety per cent. Indications for treatment are: (1) To destroy the bacteria at the seat of infection by thoroughly antisepticizing the parturient canal and by subsequently keeping it aseptic; (2) to eliminate the toxins already absorbed by brisk purgation and intracellular injection (under the breasts) of decinormal saline solution; (3) to overcome the symptoms induced by the action of toxins—viz., the increased reflex irritability of the higher nerve centres—and this is best accomplished by keeping the patient absolutely quiet in an isolated place and by chloral in very big doses, given either per os if possible, per anum, or hypodermic injection of apomorphia, hyoscine hydrobromate, or morphine; and (4) to neutralize the poison already absorbed and to immunize the body after local infection has taken place.

The Sometimes Successful Treatment of Cases of Apparently Incurable Blindness.—Clinical lecture by C. B. Taylor. The author outlines a few clinical histories of cases in which a hopeless prognosis had generally been given, and in which procedures rather infrequently used in ophthalmic practice led to remarkable and sometimes brilliant results. These measures comprised electricity, static, faradic, and galvanic; mercury in large doses, either alone or in combination with other drugs; derivatives, vascular, nervous, or both; and lastly persevering treatment along the foregoing lines with such operative procedures as were indicated in each individual case. The author adds that these agencies are merely plain, common-sense principles which all can understand, which have the sanction of experience, and which have yielded important results.

Dermatitis from Arsenic in Stockings.—By F. W. Tunnicliffe. Two cases are cited in both of which it was possible to determine by accurate chemical analysis the presence in stockings of an amount of arsenic above that allowed by law for manufacturing purposes in the matter of dyes. The arsenic used for the purpose named is generally in the form of "fuchsin red." Of the cases quoted one patient absorbed enough arsenic through the skin to give severe constitutional symptoms; in the other only intense local pain was produced when the patient stood on the feet, although no gross local inflammation was evident and systemic symptoms were wanting.

Mercury and Iodide of Potassium Given Internally with Pilocarpine Hypodermatically in Diseases of the Eyes.—By G. H. Burnhamby. Cases are reported of sclero-keratitis and of cyclo-irido-keratitis. The results were good, though the cases were still under treatment when reported. The author attributes the good effects of the drug combination named in the title to its power of arousing to excessive activity, in a vigorous and sustained manner, the normal physiological processes in diseased tissues, and thus acting so in accord with the efforts of nature as to bring about a restoration to a normal condition.

British Medical Journal, April 27, 1901.

The Dietetic Value of Sugar.—H. Willoughby Gardner gives the following as the chief points about sugar as a food: It is easily digested and absorbed. It is readily stored up as glycogen, forming a reserve of force-producing material. It is in this form readily available when required. It becomes completely oxidized without any waste and leaving no residue. Under certain circumstances it can be converted into fat and so produce heat and force. It can be called a proteid-sparing food. It is pleasant to take, acts as a relish, and stimulates the activity of the digestive processes. So it should be an admirable food for producing heat and energy. It is necessary for growing boys and girls, and their nutrition often suffers owing to a popular prejudice against it. It is valuable in cases of anæmia and for the aged. Sometimes sweets harm the teeth, but on account of impurities. Cane sugar is apt to cause an undue secretion of mucus. Those who are gouty and fat must avoid sugar as they would poison. Thin gouty patients may use it.

On Certain Practical Applications of Extract of Suprarenal Medulla.—E. A. Schafer states that this extract has a far greater power in causing contraction of the muscular tissue of the uterus, whether pregnant or non-pregnant, than any other drug having the same reputed action, and whether the extract be applied directly to the muscular tissue or be introduced into the circulation. The active principle is unaffected by the gastric juice. In post-partum cases it is better to inject it directly into the uterine cavity. The solution suitable for this injection is an infusion of dry medullary substance, gr. xxx. to the pint of water. This should be sterilized by boiling and injected while fairly hot. The extract is of great value in sudden cardiac failure, whether the result of shock or hemorrhage or of an overdose of anæsthetics. The sterilized solution may be of the strength of gr. v. to a fluidounce, and must be filtered and injected with a hypodermic syringe into a superficial vein, or in apparently hopeless cases into the heart itself.

A Preliminary Note on the Hibernation of Mosquitos.—H. E. Annett and J. Everett Dutton declare that larvæ, both Culex and Anopheles, are able to withstand a temperature of about 4° C. for a period of two weeks. There can be no doubt that mosquitos of both genera "hibernate" during the winter months in England, and it seems certain that not only the adults but also the larval forms provide for the continuation of the species during the cold weather. Among the numbers of mosquitos collected by these writers, a male was never found, and all the females used for the experiments had been fertilized. If these mosquitos are kept in a dry cage, they die in a few days, but they can probably be kept for months in a damp cage in the cold. On introducing them into a warm room they quickly become active.

Suprarenal Gland Extract in the Epistaxis of Hæmophilia.—Dan McKenzie reports the case of a hæmophilic male aged thirteen years, who had been suffering from nosebleed for some days. Tannin insufflation, calcium chloride—gr. v. in water every four hours by mouth—and plugging were tried, but all proved ineffectual. Finally, three tabloids of suprarenal gland (gr. v. each) were bruised to a powder, mixed with ℥ i. of water, and allowed to settle.

A tampon of cotton-wool soaked in the fluid was inserted into the nostril with immediate success.

French Journals.

Two Cancerous Goitres.—Maurice Patel reports these cases. The first was that of a woman aged fifty-four years. Five months before presenting herself at the hospital she began to suffer extreme pain in the left side of her head and face. A short time later a swelling appeared in the left cervical region which grew very rapidly. As long as she could remember she had had a swelling in the right cervical region which had never caused her any trouble. The menopause made no change in the size of the tumor. At the time of her appearance at the hospital she had an enormous tumor of the neck, the circumference of which was 54 cm. The head was inclined slightly to the left. The movements of rotation were very limited. The skin was darker than normal, and there were some large veins in the lower part of the tumor. The local temperature was high on simple palpation. The consistence of the tumor was firm in general. It was irregularly tesselated. The normal parts of the neck were distinguished with difficulty. Dysphagia was pronounced. Semi-solid food could scarcely pass. There was a dry cough without expectoration. The face was congested, the eyes were brilliant, with a slight degree of exophthalmus. The pulse was 96 and intermittent. There were no cardiac murmur and no tremor. The urine was normal. The general condition was bad. Finally, in a state of advanced cachexia the patient died. Post-mortem examination showed an epithelial cancer of the thyroid which had taken rise in an old cyst. There were secondary involvement of the trachea, œsophagus, and ganglia of that region, and metastasis to the lung. The second case was that of a woman who for a long time had had a goitre the size of a fist, which had never caused her the least inconvenience. Suddenly it began to grow, and although causing no pain the dyspnœa and dysphagia were intense. Finally, the neck measured 81 cm. in circumference. The patient was not very thin, but death occurred after the cancer had been growing seven months. Autopsy was not allowed. In cancer of the thyroid the general condition remains good for some time. The grave anæmia of other cancers is not met with here.—*Gazette des Hôpitaux Civils et Militaires*, March 9 and April 11, 1901.

Researches on the Etiology of Dysentery.—M. H. Comte, in the course of an epidemic of this disease, made many examinations of the stools, principally at the beginning of the attack. The glairy, blood-streaked stools of the first days were relatively poor in bacteria. The amœba was not seen, but a small bacillus occurred, sometimes in pure culture, sometimes associated with streptococci in small number, or with large bacilli. When the disease progressed, the bacteria increased in number and variety. The bacillus constantly seen was 2 or 3 μ, was contracted in the middle, so that it often looked like a diplococcus, slightly mobile in extemporaneous preparations of the stools, but very movable in bouillon. On potato and serum, the cultures looked like those of the bacterium coli. It fermented lactose, rapidly coagulated milk, gave the indol reaction, but did not stain by Gram. The writer has found the coli bacillus not only in dysentery but also in choleriform diarrhœa, which is often observed at the same time as dysentery.—*Le Bulletin Médical*, April 17, 1901.

The Serums in Therapeutics; Organic Serums.—Edmond Vidal draws the following conclusions from the study of orrho-therapy as it has been conducted in the various lines: It appears that all the serums called antitoxins do not act on the microbe nor on the toxin, but on the cells of the organism which they aid to ward off the enemy—the microbe. Consequently, the serums of immunized animals do not appear to have a certain specific action, but a general tonic action. Considering the uncertainty which still obtains in the use of animal serum in therapeutics, it is advisable for the physician to continue to employ only the serums called artificial, except in certain particular cases with definite indications.—*Le Progrès Médical*, April 13, 1901.

Inguinal Adenopathy in Visceral Cancers.—Ch. Viannay declares that the appearance of cancerous inguinal adenopathy is a sign of very grave prognosis. Cancerous glands of the groin do not demand any active treatment, because they are habitually indolent and do not cause the patient any pain. They represent a secondary lesion. If ulceration occurs the affected areas should be carefully dressed, in order to prevent the occurrence of erysipelas and other infectious complications. Quinine incorporated in the dressings is advised. At the same time the internal administration of quinine is advantageous.—*Gazette des Hôpitaux*, March 16, 1901.

Münchener medicinische Wochenschrift, April 9, 1901.

The Transfusion of Blood and its Applicability as a Curative Agent Considered from New Points of View.—A. Bier has found that the injection of small amounts of the defibrinated blood of animals differing in species from the recipient produces a hæmolytic reaction which is accompanied by general systemic effects. Prominent among these are dyspnœa and coughing, reddening and warmth of the surface, pain in the back and head, stimulation of peristalsis, and fever ushered in by a chill. With successive injections these manifestations decrease in severity until the hæmolytic powers of the animal operated upon reach such a point that a considerable amount of the foreign blood is broken down all at once, when a severe reaction is caused and subsequent injections have to be carried on with great caution. These observations were confirmed by experiments upon man, with the result that the author believes that the measure may eventually be found to have therapeutic value. The conditions it is capable of fulfilling are: (1) The possibility of producing temporary hyperæmia due to capillary congestion and involving even the most deep-seated portions of the body. Observations with drugs make it probable that these changes would be most marked in diseased tissues. (2) Great stimulation of metabolism and of the appetite. (3) The production of a high "aseptic" fever. (4) Possibly an alteration of the composition of the blood.

Multiplicity of Primary Malignant Growths.—Nehrkorn describes three cases of multiple epitheliomata which in each instance on section were found to represent different types of histological structure and may be considered as independent primary growths. Another case of multiple primary malignant disease was that of a woman who was at one sitting submitted to a resection of the rectum for melano-sarcoma and hysterectomy for adeno-carcinoma. In general, however, such coincidences are rare, and unimpeachable evidence of non-relationship between the growths can be obtained only in exceptional cases. Predisposition, to which an important rôle is ascribed in systemic disease, in these cases must remain only presumptive so long as definite knowledge of the noxa of cancer is still beyond us, and the remarkable simultaneous occurrence of malignant growths in the same individual is not explicable by any hypothesis as yet formulated. In view of the relatively excessive infrequency with which multiple primary growths are observed, we can perhaps fall back on the general laws controlling the coincidence of combined disease.

Bismuth Poisoning.—F. Mühlig reports two cases of poisoning resulting from the external application of bismuth which subsequent analysis showed to be absolutely uncontaminated. Both patients had received burns of considerable extent which were dusted freely with the subnitrate of bismuth. In the one case after nineteen days, and in the other after twelve days of this treatment, salivation accompanied by stomatitis, blue line on the gums, and dysphagia developed. In both cases complete recession of the symptoms did not occur till about a month had elapsed, and it was necessary thoroughly to curette from the wounds all traces of the application.

A New Point of View in the Treatment of Whooping-Cough.—G. Spiess believes that the laryngeal spasms of this disease are due to irritation of the peripheral endings of the sensory nerves of the larynx, and has found that they can be obviated by a more or less continuous anæsthetization or rather hypæsthetization of the laryngeal mucous membrane. This can be most advantageously done by means of insufflations of orthoform, which is but slowly absorbed by mucous membranes, with the result that its effect is protracted over a considerable length of time and the applications need repetition only once in several hours.

Observations on Diffuse Peritonitis in Appendicitis.—E. Sonnenburg gives some figures that are encouraging, inasmuch as, although the gravity of complication cannot be discounted, yet the statistics of the later years are so much more favorable than those of the previous periods that at least a moderate degree of optimism for the future seems justified. During the six years from 1894 to 1900, 150 cases of suppurative peritonitis were treated with 79 (fifty-two per cent.) cures. Dividing these into two sets, *i.e.*, those before 1897 and those after that date, we find for the first period 61 cases with 25 (forty-one per cent.) cures, and for the second term 89 cases with 54 (sixty per cent.) recoveries. In most cases a lateral incision through the flank is recommended as giving better access to the presumptive starting-point of the infection and carrying with it less risk of diffusing the process than the median operation. Drainage and irrigation of the abdominal cavity are not advocated by the author, who habitually employs extensive tamponade. Early operation is the prime factor for success; in cases in which operation does not seem wholly indicated, rest with the administration of narcotics is advised; for, although opium obscures the clinical picture, still it does tend to restrict and localize the process so that small doses of morphine are permissible.

Total Extirpation of the Stomach (Œsophago-enterostomy).—A. Bardeleben reports another case of complete gastrectomy with apparently curative result. The patient, a woman aged fifty-two years, had for a year before the operation been suffering from the usual symptom complex of gastric carcinoma, and on exploratory incision it was found that the cardia, entire anterior wall, and the pylorus, as well as a portion of the omentum, were involved. The entire stomach and some of the omentum were resected, the duodenum was closed, and a lateral anastomosis made between the œsophagus and jejunum. The patient made an uninterrupted recovery, taking small amounts of fluid by mouth on the evening of the operation, while all rectal feeding was discontinued on the third day. Since then (a period of six months) she has had no pain, feels perfectly well, has normal movements, and has gained seventeen pounds.

Two Cases of Urogenital Coli Bacillosis.—By W. Karo.

Asepsis in Neck Operations.—By O. v. Büngner.

Berliner klinische Wochenschrift, April 15, 1901.

Hyperæsthesia of the Nasal Mucosa.—B. Fränkel believes that the importance of reflex neuroses, due to the heightened sensibility of portions of the nasal mucous membrane in producing asthma, hay fever, and similar affections, has been overestimated, and that the frequency with which cauterization and other surgical measures are performed is not justified by the results. In testing for the presence of such a state the customary method of touching various areas with a probe and noting the amount of reaction produced is unreliable, since the touch sense may be independent of the reflex excitability, and besides the sensitive spot is likely to be overlooked. A better way is to employ solutions of ammonia, beginning with a one-per-cent. strength and running up to forty per cent. These are given to the patient to smell, beginning with the weakest, and the strength of the solution first producing the characteristic stinging sensation is noted. In treating these states local anæsthesia with cocaine and orthoform often gives beautiful results in selected cases, but their effect is only transitory, and the patient is often disappointed by the speedy return of his symptoms, while it is not safe to give the drugs into his own hands for habitual use. On the whole, the best results may be expected from the bromides, in gr. xv. doses three times a day, and it is particularly in periodic affections like hay fever, whose advent can usually be accurately predicted by the patient, that prophylactic treatment, begun several days before the date of the expected attack, is to be recommended.

Concerning Prompt Surgical Intervention for Intestinal Perforation in Typhoid Fever, with Relation of a Case.—By Harvey Cushing. The author gives some statistics of this operation, stating among other facts that there are now on record thirty-seven actual cases of recovery after perforative lesions, and expressing the belief that the recovery percentage will steadily increase in years to come. He suggests that in future the following classification of cases should be made: (1) Those cases, usually followed by recovery, in which the peritoneal reaction has been sufficient to keep the infection localized for a long time, including presumably many cases of appendicular origin in which the operation has consisted in evacuating an intraperitoneal abscess; (2) those cases of late operation on an advanced generalized peritonitis which rarely end in recovery, and only when the predominating organism possesses a low degree of virulence; and (3) the cases of free perforation recognized and operated upon before the production of a diffuse peritonitis, in which the prognosis is dependent upon the promptitude of the intervention and the bacteriological characteristics of the extravasated material. The case here narrated presented abdominal symptoms from the start. Local peritonitis developed with pre-extravasation symptoms supposed to be due to a small hemorrhage. Subsequent laparotomy was done (forty-five hours later), under local anæsthesia, for symptoms of collapse. The perforation was found and closed. There was a second perforation into the wound with a resulting temporary fistula, but recovery eventually ensued.

Some New Points in Tendon Surgery.—By F. S. Coolidge. The paper is an advocacy of Nicoladoni's method of transplanting the tendon of a strong healthy muscle into the tendon of a paralyzed muscle. The following are the points to be considered: (1) The time of the operation, which should not be done until the reparative process which follows an attack of infantile paralysis has nearly or quite reached its limit. (2) The amount of strength of the muscle to be grafted as compared with the work which it will be called upon to do. (3) The location of the grafting, which may be done either above or below the annular ligament, preferably above it, for then the ligament will hold the graft in place. (4) The manner of joining the tendon. It is preferable to pierce the normal tendon, pull through the paralyzed tendon, and then apply sutures, or else to cut the paralyzed tendon quite long, to fold it down and suture it to itself, first always taking a stitch at the bottom of the slit in the tendon to prevent its splitting to the end. (5) The sutures; chromicized catgut with a life of four to six weeks is preferable. (6) The post-operative treatment should consist in the application of a plaster bandage for four weeks, then massage and passive motion, usually with some appliance to keep the foot in its proper position for a couple of months more.

The Surgical Treatment of Amœbic Dysentery.—By F. W. Murray. The author notes the peculiarly destructive character of the ulcerations occurring in this disease, and claims that in order to secure recovery two conditions are necessary: (1) Cleanliness, and (2) enforced rest of the ulcerated tissues. He therefore advises the formation of an artificial anus through an inguinal colostomy, preferably on the right side. Thereby we can place the bowel at rest, and through the bowel opening we can in addition carry on a thorough and satisfactory local treatment of the colonic ulceration. The operation should be performed early in the disease, after medical treatment has had a fair trial and has failed to relieve the condition. The duration of uncomplicated cases, which are cured by medical treatment, varies from two to four to six months; and Murray recommends that if, after four months of medical treatment, the dysentery is not cured, then the case should be turned over to the surgeon. The artificial anus should be left open for a long time, several months perhaps, and its subsequent closure should not follow until it is quite certain that the ulceration is healed.

ASSOCIATION OF AMERICAN PHYSICIANS.

Sixteenth Annual Meeting, Held in Washington, D. C., April 30, May 1 and 2, 1901.

First Day—Morning Session.

The President's Address.—Dr. William H. Welch, of Baltimore, delivered this address. At the first meeting of the new century it would be appropriate, he said, to review the work of the past, but the members were there to listen to papers on actual knowledge and scientific research. He drew attention to the opportunities now offered to those desiring to take up the life and work of the medical profession. Thoroughness in laboratory training in this country compared very favorably with that of any other country. Those desiring to devote their attention to physiology, anatomy, or pathology were able to do so on account of the many positions opened to them in our colleges and institutions. It would seem that opportunities for training the physician had not kept pace with the progress in strictly scientific work.

Since the last meeting they had to mourn the loss of four of their members, three of whom had held the office of president. James T. Whittaker had been stricken down while in full possession of his powers. As an example of his ever-readiness to examine into the value and possibilities of a new scientific discovery, his hastening to Berlin immediately upon the announcement of the discovery of tuberculin by Koch was cited. James N. Da Costa had made a world-wide reputation as a teacher, author, and diagnostician. Among his many works the success of his "Medical Diagnosis" was mentioned as greater than that of any other American text-book. Samuel C. Busey was a man of lofty ideas and tireless devotion to his profession. His high standard for science would always keep his name among our peers. William H. Draper, who only the day before had been borne to his last resting-place, had presided over the first meeting of this association. Not a branch of the medical profession but had learned to honor and respect his deep learning.

Slow Pulse with Special Reference to Stokes-Adams' Disease.—Robert T. Edes, of Boston, the author of this paper, was unable to be present. He had forwarded his manuscript, but it was not read on account of the great number on the programme.

An Undescribed Cardiac Sound.—This paper was read by Dr. H. A. Hare, of Philadelphia. The discussion at the present time of any physical sign that had not been described was apparently impossible, he stated. He had no doubt that all present had heard the sound, and yet he was not familiar with any mention of it in text-books. The sound was that peculiar vibrating one occurring with systole, and heard best in an area extending from one inch to the right of the sternum to one inch to the right of the nipple, and on a level with the nipple. Sometimes it was very dry and resembled a pericardial friction sound. He was confident, however, that it was not a friction sound. It was probably due to vibrations in the chordæ tendineæ, produced by imperfect contraction of their muscular attachments, because it was not met with in feeble, irritable hearts. It was frequently found with early pulmonary tuberculosis, so frequently that he considered it indicative of that disease. It was not, however, frequent in the advanced stages of consumption. Emphatically it was not a hæmic murmur, which was generally heard elsewhere besides at the apex, and was soft and purring. This sound was like a "ching" at each systole. It was short and quick, and not changed by deep or superficial pressure of the stethoscope. It was decreased, but not obliterated, by rest. Nervousness and fear accentuated it. This was not the musical murmur described by Dr. Da Costa as resembling the cooing of a pigeon; it was not so clear and distinct. There were no subjective symptoms, as a rule.

The Frequency and the Diagnosis of the Flint Murmur in Aortic Insufficiency.—This paper was read by Dr. William S. Thayer, of Baltimore. The man for whom this murmur was named discovered it in 1862. It was loud and blubbering, like a mitral presystolic murmur. During the past eleven years a number of instances had come under his observation in Dr. Osler's wards in Johns Hopkins Hospital. Since 1889, autopsies had been performed in 74 cases. In 45 cases there had been a rumbling echoing murmur in diastole, limited to the apex. Unlike an aortic regurgitation, it was presystolic, ending in the first sound. Out of 58 aortic insufficiencies examined, 33 had the Flint murmur. In 17 of the 33 the mitral valves were absolutely normal. He drew the conclusion from these and other statistics that the Flint murmur was present in the majority of cases of aortic insufficiency. The most characteristic physical signs were to be found in the pulse, the sharp systolic shock at the apex, the mid-diastolic murmur, and the thrill in the apex region. An examination of 22 cases of mitral stenosis showed the thrill to be present in 54.5 per cent., the systolic shock in 68 per cent., and the presystolic murmur in 81 per cent. Aortic insufficiency with the Flint murmur was not so intense as the more marked murmurs of true mitral stenosis. The Flint murmur was associated with a heaving impulse. The condition of the pulse aided greatly in the making of the diagnosis. The history, too, was important. In the 33 cases with the Flint murmur, a history of rheumatism or chorea was obtained from only 13. In a larger percentage, about one-half, arteriosclerosis was present.

Dr. Cabot, of Boston, said that at the Massachusetts General Hospital he had found at autopsy the mitral valves normal in ten cases which had had the Flint murmur.

On Right-Sided Occurrence of Hydrothorax.—Dr. Alfred Stengel, of Philadelphia, read this paper. Having had at one time under observation, he stated, three cases of unilateral hydrothorax without external œdema, and being impressed with the difficulty in distinguishing such effusions from inflammatory pleural exudates, he had been led to investigate the causes of the condition. Writers, almost without exception, stated that the effusion in heart disease was always bilateral. To determine the frequency of hydrothorax and the conditions of its occurrence, he analyzed one hundred consecutive cases of cardiac disease, in which sufficient clinical and pathological information was preserved to make notes of value. He found seventeen in which the evidence proved the existence of hydrothorax. Of these seventeen, five were affected on the right side only, three on the left side, and nine were bilateral at some stage. Figures showed a very great preference of hydrothorax for the right side. This distribution was not accidental. He then reviewed the causes of dropsical effusions, mentioning obstruction to the venous circulation, lymphatic obstruction, changes in perivascular tissues, and hydræmia or anæmia. He said it would seem at first that hydrothorax without external œdema was caused by altered perivascular tissues from old pleural inflammations, with venous stenosis that had not increased sufficiently to cause bilateral pleural œdema. Some anatomical condition, however, must be sought, and two suggestions offered themselves: either obstruction of circulation in the superior vena cava, causing ob-

struction to the circulation in the right lymphatic duct, or the venous circulation in the intercostal and right pulmonary veins entering the vena azygos minor was obstructed. The former view was untenable, as the right lymphatic duct was well protected by valves; and, if this was the case, the chest, arm, and neck would be affected on the right side. The specific gravity of effusions was studied, as normal transudates ought to have higher specific gravity than that of venous obstruction. Statistics, however, did not substantiate this. The varieties of cardiac diseases in which right-sided hydrothorax had occurred was then discussed. However, in two autopsies the right ventricle, auricle, and the vena cava were unusually dilated, and there was marked backward pressure upon the root of the right lung and azygos vein. These facts, together with the anatomical studies, clearly pointed out the cause of the sole or predominant effusion on the right side.

A Case of Pneumonia Complicated by Pseudo-membranous Exudate on the Mucous Membranes of the Mouth, Tongue, Pharynx, Nares, Conjunctivæ, Glans Penis, Anus, etc., Caused by Diplococcus Pneumoniæ.—This paper was read by Dr. Charles Cary, of Buffalo. The case was remarkable in only the one respect: that this exudate was found so extensively involving the various mucous membranes. Microscopical examinations showed the diplococcus pneumoniæ to be present in all these situations. The case was reported in detail, the day of the appearance of the exudate in each locality being given. The patient evidently re-infected himself.

Exhibition of a Cardiograph and a Kymographion for Bedside Use.—By Dr. Alfred Stengel, of Philadelphia. These instruments were not presented, owing to a disappointment by the instrument maker.

Myocarditis and Fatty Degeneration of the Heart.—Dr. Beverley Robinson, of New York, said it was often most difficult to differentiate between these two affections. The diagnosis was often problematical on the most careful investigation. Fatty degeneration was not uncommon in pernicious anæmia, but not general in simple anæmias. The symptoms of cardiac weakness were slowness of the pulse, sometimes intermittence, a systolic murmur, dizziness, and perhaps fainting. He had seen patients unconscious for half an hour or more, the pulse at the wrist being very weak, and upon return to consciousness there would be found no enlargement of the heart. The diagnosis would always demand a great deal of consideration. If the patient was a high liver and took freely of alcoholic stimulants, it was reasonably sure that fatty degeneration was present. Dizziness might come on rapidly with little or no sufficient cause. This he considered evidence of a beginning of fatty degeneration. He would give in these cases iron and arsenic for the blood, intestinal antiseptics, and cardiac stimulants; oxygen also was often of marked usefulness in these cases. In senile heart, among those who had lived moderate and temperate lives, the changes were more likely to be fibroid in character. The arteries were apt to show fibroid changes, and the urine would be of a low specific gravity, without, perhaps, containing any albumin or sugar. With slight exertion or indiscretion in diet the symptoms might be brought on. The patients frequently had dizzy or fainting turns. They slept poorly, and bronchitis was likely to appear. These patients suffered from myocardial changes. In men after middle life and in women at the time of the climacteric great care should be taken in making a diagnosis. When women had a great flow at the periods of menstruation, the subsequent anæmia tended to fatty degeneration and cardiac dilatation. If under these circumstances it became necessary to administer an anæsthetic of any kind whatsoever, the greatest of care was required. This should be especially borne in mind in cases of uterine fibroids in middle-aged and corpulent women.

Hemorrhage into the Pleural Sac; a Cyst of the Omentum.—These two cases were presented by Dr. A. Jacobi, of New York. The first was that of a child admitted to Roosevelt Hospital after a prolonged illness. There had been loss of flesh, the appetite was very poor, and the child was very weak. Upon admission the temperature was 102° F. There was dulness over the right lung, extending to the fourth rib. Resection was performed under chloroform and pus evacuated to the amount of 500 c.c. Immediately a flow of blood followed. Fully 250 c.c. of blood was lost. It could be seen to be escaping from some tufts on the pleural membrane. These varied in size from 1 cm. in diameter to that of a pin's head. The necessity for immediate packing of the wound to prevent further loss of blood prevented the obtaining of a specimen for examination. The hemorrhage did not recur at subsequent dressings. A careful search for tubercle bacilli was unsuccessful. The temperature became normal in a few days, and the child made an uneventful recovery. Cases in the literature did not aid in the diagnosis. The second case had been admitted to the hospital with a diagnosis of tuberculous peritonitis. The abdomen was tapped, and the patient improved. One year later the child returned and was tapped again with apparently good results. A third time the tapping became necessary. There were no cough and no sweats, and the respirations were normal. The fluid was examined for tubercle bacilli with negative results. When a few weeks later lymph nodes appeared in the axilla, an operation was decided upon. A large multilocular cyst, containing two quarts of a clear straw-colored fluid, was removed. It was found to arise from the omentum by two pedicles. The patient had a high temperature two days after the operation, but presented no sign of inflammation at the site of the wound, and was shortly discharged from the hospital, cured.

Dr. Henry remarked that he had never seen hemorrhage into the pleural sac in tuberculosis, except in cases with scurvy, and he doubted if tuberculosis was usually a cause. Hemorrhage was quite uncommon, while tuberculous infection of the pleura was very common.

Dr. Peabody did not think hemorrhagic pleurisy with tuberculous infection was very uncommon. Very likely it was often not diagnosed, because many men recovered.

First Day—Afternoon Session.

Report of the Progress of Cases of Pernicious Anæmia Presented to the Association in 1900, and Report of a Case of Pernicious Anæmia with Diffuse Spinal-Cord Lesions, with Post-Mortem Findings.—This paper was read by Dr. Frank Billings, of Chicago. By means of carefully prepared charts he showed the changes these cases of pernicious anæmia had passed through during the past year. The blood examinations had been carried on as systematically as was possible. He drew attention to the fact that as the patient improved the megaloblasts diminished in number. This was spoken of as Von Noorden's crisis. The improvement waves were longer than at his last report. There were no new blood changes to be brought to the notice of the association. He described at length the spinal-cord lesions in his case of autopsy and demonstrated them by microphotographs.

Further Notes of a Case of Pernicious Anæmia Reported at the Meeting of 1900.—This paper was presented by Dr. F. P. Henry, of Philadelphia.

A Case of Acute Leukæmia, Presenting Some Interesting Features.—This paper by Dr. D. D.

Stewart, of Philadelphia, was not read, as he had another he was more anxious to present and he wished to help shorten a too long programme.

Acute Miliary Tuberculosis, Primarily Splenic.—This paper was read by Dr. D. D. Stewart, of Philadelphia. The disease, it was stated, was of very rare occurrence and easily overlooked. In one case mentioned, typhoid was regarded as very possible. The patient gave a negative history. After an attack of influenza and before he had become strong he was taken acutely ill. His temperature was between 101° and 103°. He had a chill daily. No red spots appeared. The spleen was easily palpated. A few weeks before death tubercle bacilli began to be suspected in the lung. The autopsy showed miliary tubercles in the spleen, lungs, and liver. The spleen was more enlarged than any other organ.

Notes on the Relapsing Fever of Hodgkin's Disease.—This paper was read by Dr. John H. Musser, of Philadelphia. He called attention to the fact that fever had long been observed as an important symptom of this disease. It was not always continuous but might be remittent. Sometimes before a paroxysm the patient had pains in the groins and became very irritable. Anæmia was very common, but the blood examinations threw no new light on its etiology. The glands in the neck and axilla might be enlarged, and the spleen usually was palpable. He concluded that the chronic recurring fever of Hodgkin's disease was in all probability tuberculous.

Dr. Welch said they had had quite a number of cases at the Johns Hopkins Hospital that had turned out to be tuberculous.

A Study of Granular Degeneration of the Red Blood Corpuscles.—This paper was read by Dr. Alfred Stengel for Drs. C. Y. White and William Pepper, of Philadelphia. These granules were described as varying in size, as being usually rounded, sometimes elongated, and either clumped or scattered. The cell substance might be normal. They might be found in nucleated cells. They were found never in fresh cells but only after staining. The literature bearing upon the subject was reviewed. Their experiments had been carried out with several classes of cases. Examinations were made of the blood of those suffering from chronic lead poisoning; of men who were constantly exposed but were not poisoned; of men exposed to high temperatures—men working before large furnaces; of those suffering from other diseases than lead poisoning, and of the blood of animals under various conditions. In the first class the granules were very constant. The coarsest granules were in excess in the worst cases of poisoning. Granules were found in all of the next class without an exception. Among the men working in iron foundries, they were found in only one person. This man had been suffering from diarrhœa, and it was thought quite probable that he had been given some lead as a medicine. It was found that within twenty-four hours after lead acetate was given, granules could be found in the blood. Attention was called to the great difficulty in staining specimens from the marrow of bones. This had been found to be due to the oil and might account for the fact that no one had hitherto made these stains.

The Toxic Origin of Neurasthenia and Melancholia.—This paper was presented by Dr. M. Allen Starr, of New York (see page 721).

The Evils Arising from Failure to Recognize the True Nature of Neurasthenia, and Some Causes of this Failure.—Dr. W. W. Johnson, of Washington, who presented this paper, had made a careful study of the life of Charles Darwin, and, beginning with a history of his great physical and mental labors during his youth, showed how he was a sufferer for much of the remainder of his life. As a youth he had been fond of athletic sports. At the age of twenty-one years he had taken up work which occupied him until he was twenty-six years old. Travelling all that time, studying and taking an unusual amount of exercise, often in the saddle for many hours at a time, with poor food and water, he had overstrained his mental and physical powers. The effects of this were shown in his after-life. He became easily fatigued. He was a great sufferer from insomnia. Later he became despondent, had a desire to die—to get rid of the pain of living. Then his mode of treatment was reviewed. It was self-treatment so far as known. He adopted a rigid programme for his time. The early recognition of the nature of the overstrain was emphasized as of great importance and the need of proper sanatoria for these cases explained. Especially trained and skilled doctors and nurses should be in charge, and no other diseases admitted.

The Acid Intoxication of Diabetes and its Relation to Prognosis.—This paper was read by Dr. C. A. Herter, of New York. He first described and illustrated the different ways of obtaining the acids in excretions. One was to balance the acids and bases. In normal urines the acids and bases were nearly alike. By tables he illustrated the amounts and nature of the acids, and then compared a normal and a diabetic urine. The apparent excess of acids in the former was 0.9143 gm. in terms of sodium, and in the latter the apparent excess of bases in terms of sodium was 5.736 gm. Another method consisted in the determination of the nitrogen of ammonia. In ten normal urines the percentages of nitrogen of ammonia ranged from 2.87 to 5.39, while in seven urines collected in diabetic coma the range of percentages was from 16.73 to 28.11. The ratio of potassium to sodium was usually about 1 to 2, while in one case of diabetic urine he found 5.10 gm. of sodium to 6.69 gm. of potassium. By dieting this was changed to 7.08 gm. and 3.30 gm. There existed a certain amount of independence between the amount of sugar and the acids in these cases.

Metabolism in Diabetic Coma, with Especial Reference to Acid Intoxication.—This paper was read by Dr. E. P. Joslin, who was introduced by Dr. Pfaff, of Boston. This was a short communication of some original research work done during the past two years. The author concluded that the most correct way was to find the excess of acids from computation of the bases.

Dr. Vaughn said there was every reason to believe that these acids did not come from the carbohydrates. He would infer that the increase of potassium came from cellular disintegration.

Dr. Herter said he thought the acids came from the nitrogenous foods.

Classification of the Intoxications from a Pathological Point of View.—This paper was read by Dr. J. George Adami, of Montreal. He first divided all poisons into exogenous and endogenous. A great deal of misinterpretation in the causes of poisoning came about through the failure to recognize the fact that the intestinal tract was outside of the body; that auto-intoxication could not, therefore, take place from the stomach or intestine or from the bladder, but that it must be set up by the action of cells within the body.

First Day—Evening Session.

A Demonstration of Some Features of Photomicrography was made by Dr. Charles S. Bond, of Richmond, Ind.

Demonstration of the Renal Lesions in Diphtheria, with a Stereopticon.—By Dr. William F. Councilman, of Boston.

Demonstration of Lantern Slides.—By Dr. H. C. Ernst, of Boston.

Demonstration of Specimens of Experimental Acute Pancreatitis.—By Drs. S. Flexner and R. M. Pearce, of Philadelphia.

Demonstration of Specimens of Hemorrhagic Pancreatitis, Human and Experimental, and of Filarial Lympho-Varix.—By Dr. William H. Welch for Dr. E. L. Opie, of Baltimore.

Demonstration of Specimens of Multiple Myelomata and of Epizootic Hemorrhagic Encephalitis.—By Dr. William H. Welch for Drs. W. G. MacCallum and Buckley.

Second Day—Morning Session.

A Study of Bubonic Plague Based upon the Outbreak in San Francisco.—The clinical aspects, the bacteriology, and the pathology were discussed by Drs. L. F. Barker, of Chicago; F. G. Novy, of Ann Arbor, and Simon Flexner, of Philadelphia, respectively.

Dr. Barker said that the classification of types and the diagnosis of the disease would be based chiefly upon the cases at San Francisco, but also upon the cases seen previously at Hong-Kong and Bombay. The present conception of the disease was that it belonged to the group of septicæmic infections, that it gave rise to a general infection without any local preponderance. There was nothing distinctly peculiar about the outbreak in San Francisco. It was the same as prevailed in many places. However, it was a significant fact that thus far there had been no outbreak among the rats. The first case had been diagnosed in March, 1900, by Dr. Wilson and Dr. Kellogg, and it was confirmed by Dr. Kinyon. Most of the cases had been among the Mongolians, only three cases having been discovered among the Caucasians. In most epidemics the majority attacked had been between the ages of twenty and thirty, but the majority here had been older. There was little or no difference as to sex. The type was bubonic in general, with one primarily septicæmic and one primarily pulmonic, and two uncertain. The onset was usually sudden, followed by chill, fever, nausea, vomiting, nervous symptoms, often delirium and coma. As a rule, within twenty-four hours a bubo might be found. Death generally occurred on the fourth to the sixth day. Those who lived after the sixth day were more likely to recover. The mode of development of bubo was peculiar: it grew very rapidly, but varied in size, that of a hen's egg being most common. It usually included a group of glands and involved surrounding tissue. The œdema was very characteristic, being more elastic and resisting than in any other glandular infection. The Chinese doctor, as soon as he discovered the bubo, put on a piece of black plaster, and thus aided in diagnosing. Pain on pressure was nearly always present. The thighs were flexed and rotated outward. Hemorrhages were not uncommon. The most frequent site for the bubo was in the groin, next in the axilla, then in the neck. The popliteal space and the elbow were rarely affected. The pneumonic type—the Black Death of the fourteenth century—was of two forms: primary, in which the bacilli entered the respiratory tract and symptoms of a croupous pneumonia resulted, or secondary, usually by aspiration. At the beginning and end of epidemics it was extremely necessary to diagnose the abortive or ambulatory forms. The urine and fæces frequently contained the bacilli a month after recovery. The diagnosis could be made with absolute certainty. Doubt on this point had done much harm. No disease was more easy to recognize if one could take all the means needed. The reader then gave a differential diagnosis between plague and those diseases with which it might most easily be confounded.

Dr. Novy said the detection of the bacilli in the bubo was difficult during life. Cultures had been successfully made from blood, but were not to be relied upon. If 1 or 2 c.c. of blood were taken, they might prove successful. In the pneumonic forms no such difficulty was met with, as the sputum was loaded with bacilli. In five out of six cases the spleen was rich in bacilli. The process of staining these bacilli and a clear description of their appearance were then given. The results of the experiments with cultures were most interesting.

Dr. Flexner first drew attention to the fact that bacilli might pass through the skin of an animal without leaving any pustule. In these cases the spread to the adjacent glands took place most rapidly, even before the first was discovered. After incision into the gland, no pathological condition could be mistaken for this disease; the most important characteristic being the amount of hemorrhage into the gland, which was very striking. This hemorrhage and the œdema were not limited to the glands, but extended into the surrounding fascia and muscles for many centimetres. The glandular enlargement was due to cellular proliferation, especially of the nodes and cords. The growth of bacteria was not so enormous in any other disease, save, perhaps, in leprosy. In the lymph sinuses might be found clumps constituting thrombi, and thus the flow of lymph was obstructed. The necrosis in the glands was variously interpreted; possibly bacteria growing in such numbers might bring about this condition. Another explanation was that the lymph channels in the walls of the blood-vessels became plugged. The changes in the other organs were taken up in turn and fully discussed.

General Sternberg said that had this epidemic occurred thirty years ago we should probably be reading in papers to-day of five hundred deaths or so. But for the fact that we had had such men to send to the front, we knew not what extent this epidemic might have reached.

Dr. Park mentioned two cases which had been discovered in New York and in which the bacilli had been found. Both resulted in recovery.

Dr. Vaughn described the case which occurred at Ann Arbor.

Dr. Parker said the country owed a debt of gratitude to Dr. Kellogg and to Dr. Kinyon for their labors in San Francisco.

Experimental Yellow Fever.—This paper was prepared by Drs. Walter Reed and James Carroll, of the United States army. These experiments were conducted at an isolated garrison, erected with the aid of General Wood. The means of isolation and all the precautions against error creeping into their deductions were described fully. They tried to produce yellow fever in three ways: by the mosquito, by subcutaneous injections of blood from yellow-fever patients, and by fomites. The success of the blood-method only aided in confirming the mosquito theory. It was shown that all mosquitos did not become infected upon biting a patient. It was proven that the bacillus of Sanarelli was not the bacillus of yellow fever. It was also proven that yellow fever was not propagated by fomites. Great stress was placed upon the necessity of diagnosing the first case. The premonitory symptoms were often not very striking, and a mild case would be hard to diagnose by an unsuspecting physician. From these experiments and other observations the opinion was offered that the time of incubation was often longer than five days.

Dr. Sternberg reviewed the time he himself had given to the study and research of yellow fever. In 1880 he attempted examinations and experiments with the blood, but with no results; and now we had it absolutely demonstrated that there was something in the blood peculiar to this disease.

Dr. Welch wished it to be known that none of these young men upon whom the experiments were made died. They were American soldiers and volunteered for this work. They should be made known as great heroes.

A Case of Malarial Nephritis with Massing of the Parasites in the Kidney.—Dr. James Ewing, of New York, presented this paper. The frequent occurrence of renal lesions in malarial fever, he stated, was described long before the discovery of the malarial parasite. Of great interest and importance were the numerous records of distinctive signs of an acute exudative process in the kidneys, usually in æstivo-autumnal cases, less often in tertian infections, and consisting in the presence in the urine of epithelial and granular casts, many blood cells, and albumin. Recovery had usually followed the acute symptoms, and therefore the lack of pathological information. In the fatal cases of pernicious malaria the conditions found in this organ had been very uniform. The lesions had been those of a severe acute degeneration of the cortical tubule cells, with moderate exudation of albumin into the tubules and glomeruli. The invariable freedom of the kidney from localization of parasites in pernicious cases could not be attributed to the phagocytic powers of this organ. It was probably due to the rapid circulation in the organ. In the reader's experience in the examination of fourteen cases of malaria he found few parasites in the renal vessels, but extensive degenerative changes. However, a case recently encountered showing clinical symptoms of acute hemorrhagic nephritis and partial suppression of urine, together with the microscopical evidence of extreme massing of parasites in the kidney, appeared to show that malarial nephritis might be caused in large part by the presence of an excessive number of parasites in the renal capillaries. The case was then described in detail. In closing the author called attention to the importance of considering the possibilities of diagnosis, during life, of this type of malarial nephritis. It would seem that it could be done from the following evidence: partial or complete suppression of urine; considerable admixture of intact red cells; a considerable proportion of albumin; many granular and epithelial and some blood casts; infected red cells, both free and adherent to casts, and the presence of pigmented leucocytes.

Septic Infection through the Stomach and Duodenum.—Dr. Walter B. James, of New York, read this paper. He said that the gastric juice and the bile were commonly supposed to protect against infection through the mucous membranes of these organs. The occurrence of septic infection during the last few years, in a number of cases in which the portal of infection had apparently been in these locations, had led him to alter his views. Bacteria living in the stomach had been demonstrated by several scientists. Therefore the conditions were present for infection should a solution in the continuity of the mucous membrane occur. A case was then described at length, in which a patient had died of an overwhelming septicæmia. The staphylococcus pyogenes aureus was found in the blood, and the post-mortem showed all organs normal with the exception of a small growth in the stomach. There were no evidences of inflammatory conditions existing outside of the stomach. The increased temperature in gastric ulcer, it had been stated, could not be due to infection through the base of the ulcer. He cited a number of cases in which the autopsy had shown the existence of a superficial ulcer of the stomach without any evidences of inflammation in other parts of the body. In connection with cancer of the stomach fever was often present. This was the case in fifty per cent. of the cases reported by Osler. Another class of cases in which he thought infection often occurred by this route was that of phlegmonous gastritis. He called attention to the case of a linear stricture on the posterior surface of the stomach which had been reported at the last meeting. In his series of cases he had omitted all with inflammatory complications.

Dr. Cabot asked if a leucocytosis was usually present in these cases.

Dr. Meltzer thought that the fact of lowered vitality and resistant powers aided in explaining the infection.

Dr. Kinnicutt said this should not be considered a terminal condition. He had watched these cases for months, and the infection appeared too early to be classed as terminal.

Two Cases of Streptothrical Infection, One Broncho-Pneumonia, the Second Abscess of the Brain.—Drs. John H. Musser and N. B. Gwyn, of Philadelphia, were the authors of this paper. The symptoms in the first case had begun with a convulsion. No further symptoms had been present. The eyes had been examined with a negative result. On the third day another convulsion was followed with delirium and coma. Spinal puncture proved of no assistance in making a diagnosis. The patient died one week after the first convulsion. Circumstances permitted of a post-mortem examination of only the head. The arteries were not diseased, and the bony canals and walls presented nothing of a pathological nature. Pus was located, however, in the brain, and smears and cultures were taken. No tubercle bacilli were discovered, and it was only after prolonged and most careful examination that the streptothrix could be demonstrated. Stained with carbol fuchsin the appearance was much like that of actinomycosis, but there were no rosettes. The second case was mentioned because the patient had an increase of temperature and pulse before signs of a bronchitis appeared. It rapidly developed into a pneumonia. Specimens of sputum showed the streptothrix.

Dr. Flexner mentioned a case which had come to autopsy at Johns Hopkins Hospital, and which would have been recorded as tuberculous infection but for a most careful examination.

The Chemistry of the Bacillus of Tuberculosis.—This paper was prepared by Drs. E. L. Trudeau and P. Levene, of Saranac Lake. The following elements were isolated and specimens exhibited: Calorin; wax, existing to the extent of thirty per cent.; cellulose; three nucleo-proteids, and five glycogens.

Second Day—Afternoon Session.

To What Extent is Urine a Suitable Soil for Bacterial Growth?—Dr. William A. Park, of New York, read this paper. After ascertaining the normal acidity of urine he had made an acid bouillon using sodium phosphate, and with this normal solution of urine had proceeded with his experiments. Among other bacteria he used the staphylococci, streptococci pyogenes aureus, gonococci, the bacilli of Eberth, and the colon bacilli. He found the percentages of acidity in which they would live and thrive. The changes in the reaction of the urine due to the presence of bacteria was also studied. He experimented furthermore with urines containing albumin and sugar. He found that individual urines presented marked peculiarities. No bacteria could be made to grow in some. In the urine of one man who was in apparently good health and was taking no drugs, and whose urine was alkaline in reaction, no bacteria could be induced to live. This peculiarity was found in some urines irrespective of their reaction. In most cases, however, the acidity was all-important in determining when bacteria would grow. The author then reviewed the therapeutic advantages of an extended knowledge upon this subject.

Orchitis Complicating Typhoid Fever.—This paper was presented by Dr. Francis P. Kinnicutt, of New York. He first reviewed the literature and drew attention to the rarity of this complication. In one series of fourteen thousand seven hundred and thirty-eight cases, no record of an epididymitis or orchitis was mentioned. During the past winter he had had two cases at the Presbyterian Hospital. Full histories of both cases were read. In each this complication had occurred after convalescence had been established. In one it had begun in the cord in the inguinal canal and extended downward involving the epididymis. No sound or catheter had been used upon the patient and there was no discharge from the urethra. The urine showed a trace of albumin, no casts, and no gonococci. There was but slight constitutional disturbance. The saphenous vein on the affected side, however, became enlarged. In the second case the cord was unaffected. The enlargement was confined to the epididymis. After having been discharged from the hospital the patient had returned with the epididymis and testicle very much swollen. Fluctuation was obtained in the testicle and pus aspirated. Examination of this showed the presence of the Eberth bacilli. The author's conclusions were that epididymitis occurring in typhoid fever was due to the Eberth bacilli; that it was usually unilateral and commonly involved the epididymis and the testicle but rarely the cord; that suppuration occurred in twenty-five per cent. of all cases; that death as a result of this complication had never been recorded.

Dr. Osler said he had a case now under observation; a curious feature being the fact that the patient left the hospital without typhoid bacilli in his urine and came back with them present. Four other cases were reported by members.

Notes on the Treatment of Some Forms of Cancer by the X-Rays.—This paper was presented by Dr. Francis H. Williams, of Boston, who stated that it had been recognized for years that by caustics or the actual cautery cancer could be more or less controlled, especially when situated upon the face. The *x*-rays might also burn, and if used in this way acted only as a caustic. He wished to report cases in which it was not used as a caustic. Burns by the *x*-rays should be avoided, and great care was necessary. His first case was that of a young man with a small, flat epithelioma of the lip. After treatment it had entirely disappeared. At present he had another cancer of the lip under treatment. This one was of four months' duration and had a penetrating odor. The odor had disappeared and the new growth was improving. Another case which showed signs of decided improvement, and was now receiving treatment, was an epithelioma of the hand in a man seventy-three years of age. This cancer measured 4 cm. by 7 cm., and nothing short of amputation would have seemed possible. The special points in regard to this treatment he would make were: absence of pain; no delay from the dread of an operation; healing without burns; improvement began quickly, and the patient was not forced to give up his daily duties. The chief objections were: the care necessary to avoid burns; the expense, and the fact that the treatment must be continued for some time.

Dr. Peabody asked if the diagnosis had been proved in every case by microscopical examination. The reader replied that all cases had been submitted to a most skilful pathologist.

Ostitis Deformans.—This paper was prepared by Drs. Frederick A. Packard and J. Dutton Steele, of Philadelphia. The first case presented was that of a patient who had been an inmate of the hospital for some time without any one's attention having been called to the existence of this disease. He was a foreigner, and besides speaking a broken English he was considered to be rather stupid. The extra large size of the head as compared with the small stature first attracted the authors' attention. The calvarium was box-shape and the face was small in comparison. In one year his head was found to increase 1 cm. in circumference; the speech becoming much more indistinct. The clavicles seemed to extend almost backward. The right forearm showed a curvature to the radial side. The elbow joints remained normal. The chest was small and narrow above and large below. The ribs were thick and heavy and almost touched the crest of the ilium. The often-noted furrow extending across the abdomen was present. The pelvis had the shape of a female rather than of a male pelvis. The femora and tibiæ were much enlarged and roughened. The hands and feet were normal. The autopsy showed a remarkable form of the calvarium. It had a bluish appearance and measured 4 cm. × 5 cm. × 2 cm. The diploë was absent except in the occipital region. The pituitary body was normal. The calvarium was presented for examination.

The Spinal Form of Arthritis Deformans.—This contribution was offered by Dr. William Osler, of Baltimore. There were, he stated, three groups to be recognized: that in which the disease was found in young children with great enlargement of the spleen; the one in which adults were attacked and atrophic changes occurred in the joints; and finally the group in which all the well-known changes occurred, as exostosis and ring-bone. The course might be acute, resembling rheumatism. Associated with spinal rigidity there were two types of cases. In the first were found rigidity, kyphosis, and nerve-root symptoms: pain and muscular atrophy. The second variety differed by additional involvement of adjacent joints, spondylitis, and the absence of the nerve-root symptoms. The question arose as to the possibility of these being different diseases. He then reviewed some cases. Two were of the first type: one had complete ankylosis of the spine, together with severe nerve-root symptoms; the second had ankylosis of the spine and such severe pains that four or five grains of morphine a day were necessary. The neurologists had been devoting attention to this type. The pain was thought to be due to thickening of the pia mater and not to the bony changes. Of the second variety, three cases were described. Two had characteristic arthritis deformans. It became an interesting question whether these were new disorders or forms of arthritis deformans. The speaker's cases bore out the idea that they were arthritis deformans. A specimen, a skeleton, belonging to the University of Buffalo, was presented. The disease had started from a gonorrhœal rheumatism. The man was under observation throughout the course of the disease, which lasted for fifteen years. Shortly before death the patient had been able to move only the tongue and the eyes. He had been fed by a tube, for the introduction of which the removal of the incisors had been necessary. A peculiar feature had been the comparatively small amount of pain. A few doses of acetanilid and whiskey was all that was given.

Dr. Lamb showed a skeleton which had come from Alaska, and was supposedly prehistoric. The ankylosis of the spine was remarkable.

Dr. Griffith presented a most interesting specimen of hyperostosis of the calvarium.

Dr. Cabot spoke of the great relief found for these cases in support. He advocated the early application of plaster.

Dr. Packard said that many cases of multiple sarcoma were called arthritis deformans.

Certain Tropho-Neuroses and their Relation to Vascular Diseases of the Extremities.—This paper was read by Dr. B. Sachs, of New York. These, he

stated, had usually been associated more with diseases of the nervous system than with diseases of the arteries. The etiological factors of Raynaud's disease and of scleroderma were considered, together with the views of S. W. Mitchell and others upon the subject. The reader said the profession had troubled itself but little about arteriosclerosis anywhere in the body except in the brain. No matter how great the sclerosis might be, some nevertheless contended that these diseases were due to some mysterious trophic disturbances. It was certain that marked changes occurred in the vessels after section of the sympathetic nerves. This was especially marked in the smaller vessels, in which the lumen might become obliterated. Might not diseases of vessels occur independently of the nervous disorders? Alcohol certainly affected vessels as well as nerves. The histories of several cases were presented.

Dr. Janeway agreed that the arteriosclerosis was certainly present and important in those diseases that we called Raynaud's and scleroderma.

Dr. Sachs said he did not mean to claim that all these diseases were due to vessel changes, but that these were an important factor.

A Case of Subcortical Glioma of the Lower Part of the Ascending Frontal Convolution: A Contribution to the Nature of the Speech Disturbance Arising from Lesions in this Situation.—This paper was presented by Dr. J. Stewart, of Montreal. The first symptom, and the only one for several months, was mutism for about half an hour a day. This was in August. In January there appeared attacks of spasmodic tics, followed by numbness in the face and arms. There were no subjective or objective disturbances in the lower limbs. Each symptom of increasing aphasia was carefully noted as it appeared. Finally, just before operation, the patient was suffering from constant headaches; spasms of the lower right side of the face, intermittent in character (other cranial nerves except the fifth were unaffected); appreciable difference in the strength of the upper and lower limbs, and a steadily increasing aphasia. He could understand all that was said, and could read, but could not articulate. The local temperature over the right side of the head was increased $\frac{1}{5}$° F. The knee jerks became exaggerated. The diagnosis was made of a tumor, probably a glioma, subcortical, and involving the lower part of the ascending frontal convolution. Operation confirmed the diagnosis. The size of the tumor was one by one and one-half inches. The recovery was slow but progressive. Speech began to return in a few days, words of more than one syllable being more difficult at first.

Personal Experiences in Cases of Jacksonian Epilepsy, with Special Reference to the Question of Treatment by Operation.—This paper was read by Dr. James J. Putnam, of Boston. In general, he stated, all agreed that operation had been valuable; as to whether cortical excision was of more value was not absolutely certain. The shock of the exposure of the cortex checked for a time the action of the disease. In operation the object was not only to remove gross sources of irritation, but the minute imperceptible ones as well. As to the removal of an epileptic centre, he doubted if we could speak of any such centre. In judging of the results of operation it should be remembered that almost all neuroses showed a tendency to remission. This was seen very remarkably in tic douloureux.

Dr. Jacobi said that in the Jacksonian form one would certainly expect a local cause to be found, but that in two autopsies performed during the past year upon undoubted cases of Jacksonian epilepsy, absolutely nothing was found.

Dr. Sachs urged immediate operation in these cases if there was to be any operation at all. He said neurologists had become a little more conservative.

The Chemical and Microscopical Results of the Examination of Three Cases of Family Periodic Paralysis.—This paper was prepared by Drs. John K. Mitchell, Simon Flexner, and D. S. Edsall, of Philadelphia. The first two of these cases were a woman and her daughter. The former found that her attacks were brought on whenever she ate abundantly, or if she ate very sweet food. The paralysis progressed gradually without her knowledge until she would find herself unable to move. The right apex was slightly affected, the pupils and reflexes were normal, and the total palsy in the seizures was complete. Her daughter, a sturdy girl, had attacks which were similar, but less severe. She had her first one when six years of age. Both of these patients found that exertion might prevent an attack. If realized in time, they could be walked off. The urine was found to be of high acidity and loaded with urates. The third patient was a man twenty-one years of age. In three generations of this family there had been five patients. The attacks were much like those of the cases cited. This patient presented the aspect of one suffering from a poison: he grew very pale, the mind remaining clear, and the paralysis becoming complete. The urine was repeatedly examined, but not again for its toxicity, as that had been done thoroughly three years before. The high acidity of the urine led to suspicion of some changes in the blood. The authors described the great care with which all these experiments were conducted. The examination of the creatin gave greater promise of some light upon the subject. It would seem that the attacks were due to metabolic disturbances, to a reduction in the formation of creatin, and not to a retention, as is the case with uric acid in gout. The first patient had made an interesting discovery, that the citrate of potassium was of very effectual use. It would not postpone an attack, but by a large dose the worst seizure might be terminated within an hour. The authors had experimented with the other salts of potassium, but none of them acted the same.

Dr. Putnam had tried potassium citrate unsuccessfully in a case he had had of this disease.

The Heredity of Appendicitis.—This compilation of statistics was prepared and exhibited by Dr. F. Forchheimer, of Cincinnati.

Third Day—Morning Session.

Some Observations Made in a Case of Diverticulum of the Œsophagus.—Dr. Franz Pfaff, of Boston, read this paper. The case was seen for the first time four years ago. The patient had been losing weight for some time, had regurgitation of food, a sense of oppression at the pit of the stomach, and was constantly growing weaker. His loss of weight had during the past few weeks become so rapid that his friends were greatly alarmed. The attending physician had been unable to find any disease, and the author's examinations were equally unsuccessful. Examinations of the stomach were entered upon. No indigestion was demonstrable, but large amounts of muscular fibre were recovered. A probable diagnosis of spasm of the stomach was made, and the patient advised not to masticate his food but to feed himself with the stomach tube, which he was taught to manipulate. Instead of within a few weeks the patient did not report until the end of three years. He had used the tube all of this time. Whenever he attempted to masticate his food he had had a return of the symptoms. Further examinations were made. After twenty-four hours' fasting, no pepsin, no acids, but muscular fibres were found. Clearly these were not gastric contents, and the diagnosis of a diverticulum was established. The following facts were of great interest: the slow formation of the diverticulum; no history of injury,

and no history of disease. The patient had not even had the customary diseases of children; he had never been ill in his bed for twenty-four hours. The exclusion of saliva from the process of digestion, during tubal feeding, had not interfered with digestion. The patient was increasing most markedly in weight. The diverticulum was not increasing in volume but seemed to be changing in position. The tube must now enter the diverticulum before he could pass it, and he did not need to do so before. It had been found that quite an amount of carbohydrates was digested in the œsophagus—but experiments with lactose, and the much more easily diffusible sodium chloride, showed that absorption did not take place in this part of the intestinal tract. In another case the diverticulum was becoming more and more dilated, and eventually it would be impossible to pass the tube into the stomach. The possibility of relief and cure being had by surgery was to be considered. There was no operation mentioned in the literature.

The Importance of a Recognition of the Significance of Early Tuberculosis in its Relation to Treatment.—This paper was presented by Dr. Edward L. Trudeau, of Saranac Lake. He said it would seem to be unnecessary to emphasize this point. There was now ample evidence of the curability of this disease. The prognosis depended in great part upon the stage at which the disease was discovered. Persistent slight cough, loss of weight, and a constant slight rise of temperature in the afternoon or evening pointed too plainly, even in the absence of abnormal pulmonary signs. There might even be miliary tubercles in the lungs when there were no appreciable physical signs. When bacilli were found there was, of course, no plea for a mistaken diagnosis, but the physician should not wait until he found them. They did not appear in the sputum until ulceration began. The history and subjective symptoms, aided by the *x*-ray, helped to an early diagnosis. The tuberculin test was most valuable but by no means always necessary. This test was especially useful in incipient cases. The number of unsuspected cases of tuberculosis might be imagined when one remembered that Beck got the tuberculin reaction in twenty-five per cent. of twenty-five hundred cases in Berlin, and one of the doctors present had recently stated that in seventeen per cent. of autopsies upon patients who had died of diphtheria, he found unsuspected tubercles. The responsibility of the physician in these cases was not generally realized. Patients were often deceived as long as possible, and until too late to offer much hope by treatment in a proper sanatorium. Not less than seventy per cent. of those who applied at Saranac Lake had had the disease for a long time. The final results looked for as an outcome of the great impetus now given to the building of cottages and sanatoria for tuberculous cases would not be nearly so grand as expected unless the disease was more often diagnosed while in the first stages.

A Study of a Series of Cases of Burns.—This paper was read by Dr. J. George Adami for Dr. J. McCrae, of Montreal. By means of an enlarged micro-photograph of a stained specimen, the reader was able to demonstrate the characteristic changes of "focal necrosis." A series of thirteen cases was reviewed. Four of these had come to the post-mortem table, and from one other glands had been obtained for examination. Only one had presented a duodenal ulcer. A detailed report was given of the conditions found in each organ. In no one of the cases were the kidneys unaffected. Attention was called to the great contrast between the central foci and the surrounding tissue as brought out in the illustration. In the central portion were large cells, some triangular, others square, and some nearly circular in outline. The rapid disappearance of the débris in these cases could be explained only by a phagocytosis.

Dr. Flexner thought the most remarkable feature was the similarity which had been shown in the findings of autopsies upon subjects dying of burns and those which had been found in animals dying of diphtheria. If in burns there was a true toxæmia it might throw great light upon the cause of death in these cases.

Dr. Welch said that the view that the nuclear fragments were the result of the digestion of lymphoid cells by phagocytes was harder to believe than that the toxins were at the bottom of it all and caused the primary changes.

Hæmolysis.—This paper was presented by Dr. S. J. Meltzer, of New York. Before giving the results of his own researches, he presented a review of the recent studies in hæmolysis. The normal blood of one animal was often detrimental when introduced into the blood of another. In his own experiments he used defibrinated blood. Serum lost hæmolytic action by being heated to 55° C., and also when kept for eight or ten days. His recent studies had been devoted to the effect of the peritoneum upon the hæmolysis of serum. The normal peritoneal exudate did not contain any hæmolytic element. He described at length his mode of procedure, and pictured the possibilities of further work on the subject.

The following papers were then read by title, and will be incorporated with the reports of the Association:

"The Relative Prevalence of Bright's Disease in New York, London, and Berlin," by Dr. Hermann N. Biggs, of New York. "Lithæmic or Recurrent Coryza," by Dr. B. K. Rachford, of Cincinnati. "A Further Report on a Case of Presystolic Mitral Murmur Associated with Systolic Tricuspid Murmur Complicating Pregnancy, Reported to the Association in May, 1899," by Dr. James Tyson, of Philadelphia. "The Extension of Aortic Aneurisms into and between the Walls of the Heart and Dissecting Aneurism of the Heart," by Dr. Ludvig Hektoen, of Chicago. "A Study of Bacteria Isolated from Cases of Dysentery," by Dr. F. F. Wesbrook, of Minneapolis. "Sarcosporidia of the Mouse (Sarcocystis muris) Transmitted Directly by Feeding Muscular Tissue," by Dr. Theobald Smith, of Boston. "The Toxin of the Colon Bacillus," by Dr. Victor C. Vaughn, of Ann Arbor, Mich. "Report of a Case of Spondylosis Rhizomelia, with Autopsy," by Dr. Charles L. Dana, of New York. "A Product of Bacillus Pyocyaneus Resembling Vegetable Gum," by Dr. A. C. Abbott, of Philadelphia. "The Relation of the Tracheal Tug to Fixation and Elasticity of the Left Lung," by Dr. Henry Sewell, of Denver, Col.

This meeting of the association closed with the election of officers. The following men were chosen: *President*, Dr. James C. Wilson; *Vice-President*, Dr. James Stewart; *Recorder*, Dr. S. Solis-Cohen; *Secretary*, Dr. Henry Hun; *Treasurer*, Dr. J. Crozer Griffiths; *Councillors*, Dr. Frank Billings, Dr. Francis P. Kinnicult; *Representative on Executive Committee of Congress*, Dr. William Osler; *Alternate Representative*, Dr. Francis H. Williams.

Salicylates and Metabolism.—The influence of salicylates upon the body metabolism has been investigated by F. W. Goodbody. He finds that sodium salicylate causes an increase in the quantity of urine excreted, and in the specific gravity; the latter increase being principally due to the increased elimination of the nitrogenous substances, especially of the urea. The drug does not seem to have any influence on general metabolism, so far as the adoption of proteids and fats is concerned; but it increases the breaking up of proteids in the body.—*Journal of Physiology.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, April 16, 1901.

E. Franklin Smith, M.D., Chairman.

Potain's Simple and Accurate Method of Percussion of the Heart, with Post-Mortem Verification.—Dr. George M. Converse read a paper with this title (see page 722).

Dr. Judson Daland, of Philadelphia, said that in practice one was often greatly disappointed at the results of determining the deep area of cardiac dulness by percussion. This was especially true of cases in middle life, because of the other modifying influences, such as emphysema. He agreed with the author as to the great importance of a single isolated percussion stroke, as well as concerning the recognition of the changes in pitch rather than changes in intensity.

Dr. Andrew H. Smith said that for many years he had practised with satisfaction auscultatory percussion for determining the deep area of cardiac dulness, and had done this by scratching with the finger on the chest wall instead of striking the chest. By this method it was not very difficult to distinguish the outlines of the heart and also of the adjacent organs.
